Preface

The AIEE *Transactions* for 1958 (volume 77) is published in three parts: Part I. Communication and Electronics; Part II. Applications and Industry; and Part III. Power Apparatus and Systems. The papers in each of the three parts are classified according to subject matter as follows:

Part I. Communication and Electronics

- Aircraft and Flight Test Instrumentation
- Basic Sciences
- Communication Switching Systems
- Communication Theory
- Computing Devices
- Data Communication
- Electrical Insulation
- Electrical Techniques in Medicine and Biology
- Electronic and High Frequency Instruments
- Electronics
- Indicating and Integrating Instruments
- Magnetic Amplifiers
- Nucleonic and Radiation Instrumentation
- Nucleonics
- Radio Communication Systems
- Recording and Controlling Instruments
- Semiconductor Metallic Rectifiers
- Solid State Devices
- Special Instruments and Auxiliary Apparatus
- Telegraph Systems
- Telemetering
- Television and Aural Broadcasting Systems
- Wire Communication Systems

Part II. Applications and Industry

- Air Transportation
- Chemical Industry
- Domestic and Commercial Applications
- Electric Heating
- Electric Welding
- Feedback Control Systems
- General Industry Applications
- Industrial and Commercial Power Systems
- Industrial Control
- Industrial Power Rectifiers
- Land Transportation
- Marine Transportation
- Metal Industry
- Mining Industry
- Petroleum Industry
- Production and Application of Light

Part III. Power Apparatus and Systems

- Insulated Conductors
- Power Generation
- Power System Communications
- Protective Devices
- Relays
- Rotating Machinery
- Substations
- Switchgear
- System Engineering
- Transformers
- Transmission and Distribution

- Education
- Research
- Safety

Each part has been indexed separately in the back of that particular part. The three parts are not cross-referenced; hence the user should determine first whether the subject matter of the paper desired is in the field of communication and electronics, applications and industry, or power apparatus and systems. Papers are listed in the subject index under several key words in the titles. The original numbers assigned to the papers are given in the author index. Volume 77 contains the technical papers and related discussions presented at these meetings:

1. Winter General Meeting, New York, N. Y., February 2–7, 1958.
2. Middle Eastern District Meeting, Washington, D. C., April 28–30, 1958.
3. Great Lakes District Meeting, East Lansing, Mich., May 5–7, 1958.
4. East Central District Meeting, Huntington, W. Va., May 13–15, 1958.
5. Summer General Meeting and Air Transportation Conference, Buffalo, N. Y., June 22–26, 1958.
6. Pacific General Meeting, Sacramento, Calif., August 19–22, 1958.
7. Fall General Meeting, Pittsburgh, Pa., October 13–15, 1958.

Statements and opinions given in the papers and discussions published in *Transactions* are the expressions of the contributors for which the American Institute of Electrical Engineers assumes no responsibility.

Communication and Electronics Index for 1958

1. Technical Subject Index

Abnormal Corona, Some Measurements of. Penney, Hewitt....319–27
A-C Computers, A Differentiator for. Johnson....1–4
A-C Controlled Magnetic Amplifiers. Lehtonen, Cronauer....476–80
Accuracy and Speed in Analog-to-Digital Transducer Measurements, Relay Scanning Design Technique Generates High. Kay....248–50
Accurate Determination of Capacitance by Conjoining Analytical and Analog Techniques. Horgan, Pesavento....397–400
Accurate to 0.1 Per Cent, An Analog Frequency Measuring Circuit. Mitchell....983–5; disc. 985
(Air Force) Automatic Telegraph Switching System Plan 55-A. Vernam....239–47
Air–Ground Telephone Service Trial, Public. Augustus....926–30
Airborne Teletypewriter AN/AGC-1. Michals..234–9
Amplifier, A Stabilized D-C Differential Transistor. Depian, Smith....157–9
Amplifier as a Laboratory Tool, The Operational. Pfeiffer....947–51; disc. 951
Amplifiers Using Dynistors or Trinistors, Linear Power. Hierholzer....892–8
Amplifiers with Random Noise Signals, Performance of Class B Audio. Usher....939–43
Amplitude Random Function Generator, A Constant-. Hellwarth....443–52
Amplitude-Stabilized Bridged-T Oscillator, An. Enslein....75–9
AN/AGC-1, Airborne Teletypewriter. Michals..234–9
Analog Computer Study of the Transient Behavior and Stability Characteristics of Serial-Type Digital Data Systems, An. Elgerd....358–66; disc. 366
Analog Computer Study of the Transient Performance of a Dual Cycle Boiling Water Reactor Nuclear Power Plant. Leiby....17–25
Analog Computers, Matrix Programming of Electronic. Horn, Honnell....420–6; disc. 426
Analog Frequency Measuring Circuit Accurate to 0.1 Per Cent, An. Mitchell....983–5; disc. 985
Analog Techniques, Accurate Determination of Capacitance by Conjoining Analytical and. Horgan, Pesavento....397–400
Analog-to-Digital Transducer Measurements, Relay Scanning Design Technique Generates High Accuracy and Speed in. Kay....248–50
Analysis Applied to the Saturable Reactor, Block-Diagram Method of. Hubbard....57–64; disc. 65
Analysis of Logical Networks, Matrix. Schubert....10–13
Analysis of Nonresonant Charging Circuit for Magnetic Pulse, Generator. Weinberg....271–7
Analysis of Redundancy Networks, The. Moskowitz....627–32
Analytical and Analog Techniques, Accurate Determination of Capacitance by Conjoining. Horgan, Pesavento....397–400
Antenna, A Quadruplexer Allowing the Simultaneous Transmission of Two Complete Television Stations Using a Common. MacKimmie....787–91
Antenna System, A New Broad-Band Microwave. Friis, May....97–100
Apparatus, Philosophy of Applying Digital Computers to the Design of Electric. Abetti, Cuthbertson, Williams....367–77; disc. 377
Application of Negative-Impedance Repeaters on Long Rural Telephone Lines, The. Uthlaut....230–4
Application of Zener Diodes to Expanded Scale Instruments, On the. Corson....535–9
Applications of Nonlinear Magnetics. Storm....380–8; disc. 388
Assessment of Effects of Delay Distortion in Data Systems. Fowler, Gibby....918–23
Attenuation at 11 Kmc and Some Implications Affecting Relay System Engineering, Radio. Hathaway, Evans....930–8; disc. 1061
Audio Amplifiers with Random Noise Signals, Performance of Class B. Usher....939–43
Automatic Control of Electrical Precipitation Rectifiers. Van Hoesen, White, Hall....126–8
Automatic Mobile Telephone System. Dimmer..723–6
Automatic Telegraph Switching System Plan 55-A. Vernam....239–47
Avalanche Transistors, Theory of Transient Build-up in. Shockley, Gibbons....993–8

B

Balancing Reactors for Semiconductor Rectifiers, Current-. Dortort....452–6; disc. 456
(Basic Sciences) A Generalization of the Calculus of Finite Differences to Nonuniformly Spaced Variables. Kron....539–44
(Basic Sciences) Accurate Determination of Capacitance by Conjoining Analytical and Analog Techniques. Horgan, Pesavento....397–400
(Basic Sciences) An Electric Circuit Theory Approach to Finite Difference Stability. Karplus....210–13
(Basic Sciences) Certain Applications of Matrices to Circuit Theory. Pipes....251–6
(Basic Sciences) Matrix Analysis of Logical Networks. Schubert....10–13
(Basic Sciences) Matrix Programming of Electronic Analog Computers. Horn, Honnell....420–6; disc. 426
(Basic Sciences) Measurement of the Scattering Matrix with an Intervening Ionosphere. Bryak....611–12
(Basic Sciences) Reliable Stochastic Sequential Switching Circuits. Mullin....606–11
(Basic Sciences) Subharmonics in Iron-Cored Reactor Oscillatory Circuits. Mostafa, El-Karaksi..104–13
(Basic Sciences) The Numerical Evaluation of Expressions Involving Complete Elliptic Integrals. Grover....496–502
Basis for Transmission Performance Objectives in a Telephone Communication System, A. MacAdam....205–08; disc. 208
Behavior of the Ferroresonant Series Circuit Containing a Square-Loop Reactor. Dennard....903–11
B-H Loops on Magnetic Amplifiers, Reactions of Bistable. Morgan....586–90
Bibliography, Magnetic Amplifier—1951-1956. (Committee Report)....613–27
Bibliography, 1957 Magnetic Amplifier. (Committee Report)....1051–7
Binary Code, An Experimental Study of a. Peterson....388–92; disc. 392
Binary Communication Feedback Systems. Harris, Hauptschein, Morgan, Schwartz....960–9
Binary Symmetric Channel, On Coding for the. Fontaine, Peterson....638–46; disc. 646
Binary Symmetric Decision Feedback Systems. Harris, Morgan....436–43
Bistable B-H Loops on Magnetic Amplifiers, Reactions of. Morgan....586–90
Bits of Information. Zamanakos....197–201
Block-Diagram Method of Analysis Applied to the Saturable Reactor. Hubbard....57–64; disc. 65
Block Length for Data Transmission with Error Checking, Optimum. Wood....855–61
Boiling Water Reactor, An Electronic Feedwater Control System for the Experimental. Morse, Brey....679–83
Boiling Water Reactor Nuclear Power Plant, Analog Computer Study of the Transient Performance of a Dual Cycle. Leiby....17–25
Branch Exchanges, A New Small Crossbar Telephone System for Private. Abbott....911–18
Bridged-T Oscillator, An Amplitude-Stabilized. Enslein....75–9
Broad-Band Microwave Antenna System, A New. Friis, May....97–100
Broadcasting, Video Testing Techniques in Television. Ste-Marie....26–33
Build-up in Avalanche Transistors, Theory of Transient. Shockley, Gibbons....993–8

C

Cable Carrier System, A Transistorized Repeater for Use with the 45BN. Babin, Fish....41–9
Cable Carrier System, Determination of the Least First Cost of a. Krzyczkowski....778–82; disc. 782
Cable Telegraphy, An Improved 6-Channel Time Division Multiplex for Submarine. Wilder....217–22
Cables and Methods Taken to Improve Them, Study of Return Losses on Loaded Trunk. Speake....201–04; disc. 204
Cables, Surge Measurement Errors Introduced by Coaxial. Park....343–7; disc. 347
Calculation of Network Functions Used in Loss Formula Studies, Digital. Ferguson, Long, Rindt....647–52; disc. 652
Calculation of Transient Performance of the Primary Coolant System in a Water Reactor, Digital. Lewis....1036–43
Calculus of Finite Differences to Nonuniformly Spaced Variables, A Generalization of the. Kron..539–44
Canada TD-2 System, The Simultaneous Transmission of Television and Telephone Multiplex Over a Single Microwave Channel on the Trans-. Curtis, Strahlendorf, Wade....185–90
Capacitance by Conjoining Analytical and Analog Techniques, Accurate Determination of. Horgan, Pesavento....397–400
Carrier Repeater for Military Use, A Frequency-Converting Telephone. Goltsos, Johnston, Anderson....432–6
Carrier System, A Transistorized Repeater for Use with the 45BN Cable. Babin, Fish....41–9
Carrier System, Determination of the Least First Cost of a Cable. Krzyczkowski....778–82; disc. 782
Carrier System, Insertion Loss Filter Design Applied to Transistorized. Winkler....519–24
Carrier System, The ON/K. Masters....806–10
Carrier Systems, A New Method of Frequency Error Correction in. Stachiewicz....175–80
Carrier Telephone System, Type OJ. Coy, Kelsey, Nicholls....810–17
Central Station Power, Organic-Moderated Reactors for. Parkins, Weisner....985–93
Certain Applications of Matrices to Circuit Theory. Pipes....251–6
Channel, On Coding for the Binary Symmetric. Fontaine, Peterson....638–46; disc. 646
Channel on the Trans-Canada TD-2 System, The Simultaneous Transmission of Television and Telephone Multiplex Over a Single Microwave. Curtis, Strahlendorf, Wade....185–90
Channels for SAGE Data Systems, Communication. James....838–43
Characteristics of Magnetic Amplifiers Utilizing Square-Loop Core Material and Square-Wave Supply Voltage. Britten....590–7; disc. 597
Characteristics of Serial-Type Digital Data Systems, An Analog Computer Study of the Transient Behavior and Stability. Elgerd....358–66; disc. 366
Charging Circuit for Magnetic Pulse Generator, Analysis of Nonresonant. Weinberg....271–7
Chesapeake Bay, Dial Telephone Service for Smith Island, an Isolated Community in. Littleton....923–6
Circuit, A Magnetic Amplifier Commutating and Pulse-Width Encoding. Lucke....884–92
Circuit Accurate to 0.1 Per Cent, An Analog Frequency-Measuring. Mitchell....983–5; disc. 985
Circuit Containing a Square-Loop Reactor, Behavior of the Ferroresonant. Dennard....903–11
Circuit for Magnetic Pulse Generator, Analysis of Nonresonant Charging. Weinberg....271–7
Circuit, The Ferroresonant. Kelly....843–8; disc. 1061
Circuit Theory Approach to Finite Difference Stability, An Electric. Karplus....210–13
Circuit Theory, Certain Applications of Matrices to. Pipes....251–6
Circuits in Independent Telephone Company Areas: Transmission Considerations from the Direct Distance Dialing Standpoint, Dial Switching of Toll. Petrie....481–5
Circuits, Minimization of Components in Electronic Switching. Beatson....283–91; disc. 291
Circuits, Reliable Stochastic Sequential Switching. Mullin....606–11
Circuits, Subharmonics in Iron-Cored Reactor Oscillatory. Mostafa, El-Karaksi....104–13
Class B Audio Amplifiers with Random Noise Signals, Performance of. Usher....939–43
Clocks for Data Transmission, Synchronized. Edson, Flavin, Perry....832–6
Coaxial Cables, Surge Measurement Errors Introduced by. Park....343–7; disc. 347
Code, An Experimental Study of a Binary. Peterson....388–92; disc. 392
Code Construction, Diagrammatic Methods of. Clark....817–23
(Coding) Bits of Information. Zamanakos....197–201
Coding for the Binary Symmetric Channel, On. Fontaine, Peterson....638–46; disc. 646
(Committee Report) Magnetic Amplifier Bibliography—1951–1956. (58-996)....613–27
(Committee Report) 1957 Magnetic Amplifier Bibliography. (58-1328)....1051–7
(Committee Report) Proposed Standard Terms and Definitions for Magnetic Amplifiers. (58-175)....429–31; disc. 431
(Committee Report) Proposed Standards for Core Test Methods for Toroidal Magnetic Amplifier Cores. (58-71)....524–31

(Committee Report) The Influence of Water Resistivity and Precipitation Rate Upon 60-Cycle Wet Flashover Voltage. (58-27)......350–7; disc. 357
Communication Channels for SAGE Data Systems. James..............................838–43
Communication Feedback Systems, Binary. Harris, Hauptschein, Morgan, Schwartz............960–9

Electric Hygrometer. Meiklejohn............302–05
Electric Networks, Logic for Applying Topological Methods to. Byerly, Long, King.............. ....657–65; disc. 665
Electrical Features of Indian Point Nuclear Electric Generating Station. Reimers............879–84
Electrical Precipitation Rectifiers, Automatic Control of. Van Hoesen, White, Hall................126–8
Electroluminescent Digital Indicator With Elpak Translation Logic, An. Sack..................113–18
Electronic Analog Computers, Matrix Programming of. Horn, Honnell..................420–6; disc. 426
Electronic Feedwater Control System for the Experimental Boiling Water Reactor, An. Morse, Brey.. 679–83
Electronic Recorder, Digital and Pictorial Photographic. McPherson, Sonderby...........194–6
Electronic Switching Circuits, Minimization of Components in. Beatson...........283–91; disc. 291
Electronic Transformers, An Experimental Study of Magnetic Materials for Use in Ultrahigh-Temperature. Harms..................181–4; disc. 184
(Electronics) A Constant-Amplitude Random Function Generator. Hellwarth..................443–52
(Electronics) A Stable Direct-Coupled Transistor Servo Preamplifier. DeSautels..................943–7
(Electronics) A Stabilized D-C Differential Transistor Amplifier. Depian, Smith................157–9
(Electronics) An Amplitude-Stabilized Bridged-T Oscillator. Enslein..........................75–9
(Electronics) An Analog Frequency Measuring Circuit Accurate to 0.1 Per Cent. Mitchell............ ....983–5; disc. 985
(Electronics) Automatic Control of Electrical Precipitation Rectifiers. Van Hoesen, White, Hall...126–8
(Electronics) Design Criteria for Low-Level Second-Harmonic Magnetic Modulators. Kletsky.1013–19
(Electronics) Performance of Class B Audio Amplifiers with Random Noise Signals. Usher.......939–43
(Electronics) Some Measurements of Abnormal Corona. Penney, Hewitt........................319–27
(Electronics) Spinning Disk Random Selectors. Roberts 755–60
(Electronics) The Diode Reactance Modulator. Montgomery..................................980–3
(Electronics) The Ferroresonant Circuit. Kelly....... ....843–8; disc. 1061
(Electronics) Transistor Phase-Locked Oscillators. Edwards, Golubjatnikov, Brady..........1043–51
Elements, The Design of Function Generators Using Short-Time Memory Devices and Nonlinear. Revay, Ford..........................143–52
11 Kmc and Some Implications Affecting Relay System Engineering, Radio Attenuation at. Hathway, Evans.......................930–8; disc. 1061
Elimination of Magnetic-Amplifier Control Circuit Inductance. Chandler, Downing.......... ....550–6; disc. 556
Elliptic Integrals, The Numerical Evaluation of Expressions Involving Complete. Grover.......496–502
Elpak Translation Logic, An Electroluminescent Digital Indicator with. Sack..................113–18
Encoding Circuit, A Magnetic Amplified Commutating and Pulse-Width. Lucke................884–92
Encoding for Text and Picture Communication, Statistical. Michel..........................33–6
Engineering Problems, The Practice and the Economics of Applying Digital Computers to. Abetti, Williams ....331–41; disc. 341
Engineers to the Appreciation of Magnetic Amplifier Problems, Introducing Young. Finzi......119–26
Engineers, Willamette Valley Radio System for the United States Corps of. Pedersen, Marihart...... 401–06
Equipment, Stand-by Power for Pole-Mounted. Jamieson..................................774–8
Equipment, Wide-Band Ultrahigh-Frequency Over-the-Horizon. Felsenheld, Havstad, Jatlow, LeVine, Pollack..................................86–93
Error-Checking for 5-Channel Telegraphic Tape. Barbeau..................................190–3
Error Checking, Optimum Block Length for Data Transmission with. Wood..............855–61
Error Correction in Carrier Systems, A New Method of Frequency. Stachiewicz................175–80
(Error Detecting) Bits of Information. Zamanakos.... 197–201
Errors Introduced by Coaxial Cables, Surge Measurement. Park..................343–7; disc. 347
Evaluation of Expressions Involving Complete Elliptic Integrals, The Numerical. Grover.......496–502
Evaluation of Single Phase Metering Practices Based on Meter Performance and Load Characteristics. Vanderleck..................727–38; disc. 738
Exchanges, A New Small Crossbar Telephone System for Private Branch. Abbott..............911–18
Expansion of the Pacific Coast Microwave Network, The. Kuck..................................898–903
Experimental Boiling Water Reactor, An Electronic Feedwater Control System for the. Morse, Brey.. 679–83
Experimental Study of a Binary Code, An. Peterson... ....388–92; disc. 392
Experimental Study of Magnetic Materials for Use in Ultrahigh-Temperature Electronic Transformers, An. Harms..................181–4; disc. 184
Expressions Involving Complete Elliptic Integrals, The Numerical Evaluation of. Grover........496–502

F

Facility, A Precision, Guarded Resistance Measuring. Wyeth, Higley, Shirk............471–5; disc. 475
Factors Affecting the Use of Over-the-Horizon Links in Telecommunication Networks. Parry.....485–96
Failure in Semiconductor Rectifiers, Forward Current Surge. Gentry................746–50; disc. 754
Failure-Rate Studies on Silicon Rectifiers. Bechtold, Hanks..................................49–56
Fast-Response Full-Wave Magnetic Amplifier, A. Lynn..................................37–41
Fast-Response Magnetic Amplifiers, Volt-Second Transfer Efficiency in. Pula:
  Part I..................................861–7
Fault Protection for Semiconductor Rectifiers, The Current Limiting Fuse as. Gutzwiller............. ....751–4; disc. 754
Feedback in Magnetic Amplifiers, On. Finzi, Suozzi:
  Part I. Single Feedbacks.......1019–30; disc. 1030
Feedback Factor of Self-Balancing Magnetic Amplifiers, The Effective. Geyger..................66–9
Feedback Systems, Binary Communication. Harris, Hauptschein, Morgan, Schwartz..........960–9
Feedback Systems, Binary Symmetric Decision. Harris, Morgan..................................436–43
Feedwater Control System for the Experimental Boiling Water Reactor, An Electronic. Morse, Brey..... 679–83
Ferroresonant Circuit, The. Kelly....843–8; disc. 1061
Ferroresonant Series Circuit Containing a Square-Loop Reactor, Behavior of the. Dennard.......903–11
Field Strength in Oersteds Near Large Rectangular Conductors, Magnetic. Miller.......726–7; disc. 727
Filter Design Applied to Transistorized Carrier System, Insertion Loss. Winkler................519–24
Finite Difference Stability, An Electric Circuit Theory Approach to. Karplus................210–13
Finite Differences to Nonuniformly Spaced Variables, A Generalization of the Calculus of. Kron...539–44
Fins, Thermal Impedance of Cooling. Diebold, Luft... ....739–45; disc. 745
First Cost of a Cable Carrier System, Determination of the Least. Krzyczkowski.......778–82; disc. 782
Five-Channel Telegraphic Tape, Error-Checking for. Barbeau..................................190–3
Flashover Voltage, The Influence of Water Resistivity and Precipitation Rate Upon 60-Cycle Wet. (Committee Report)..................350–7; disc. 357
Flux-Gate Magnetometers, Self-Balancing. Geyger... 213–16
Ford Nuclear Reactor, The Design of a Pile Oscillator for the. Stone, Kerr..................1003–06
Formula Studies, Digital Calculation of Network Functions Used in Loss. Ferguson, Long, Rindt....... ....647–52; disc. 652
Forward Current Surge Failure in Semiconductor Rectifiers. Gentry..................746–50; disc. 754
Four-Wire Y 3-Phase System, Watt-Hour Meter for Two Phases of a. McQuarrie.........152–5; disc. 155
Frequency-Converting Telephone Carrier Repeater for Military Use, A. Goltsos, Johnston, Anderson.... 432–6
Frequency Error Correction in Carrier Systems, A New Method of. Stachiewicz................175–80
Frequency Measuring Circuit Accurate to 0.1 Per Cent, An Analog. Mitchell...........983–5; disc. 985
Frequency Modulation Digital Subset for Data Transmission Over Telephone Lines, A. Weber..867–72
Frequency Over-the Horizon Equipment, Wide-Band Ultrahigh-. Felsenheld, Havstad, Jatlow, Levine, Pollack..................................86–93
Full-Wave Magnetic Amplifier, A Fast-Response. Lynn..................................37–41
Function Generator, A Constant-Amplitude Random. Hellwarth..................................443–52
Function Generators Using Short-Time Memory Devices and Nonlinear Elements, The Design of. Revay, Ford..................................143–52
Function Tables in Digital Control Computers. Shubert..................................316–19
Functions in Magnetic-Amplifier Analysis, Core-Reset. Feth:
  Part I. A Core Reset Function....503–09; disc. 509
  Part II. Determination of Amplifier Performance... 510–19
Functions Used in Loss Formula Studies, Digital Calculation of Network. Ferguson, Long, Rindt....... ....647–52; disc. 652
Fundamental Aspects of Ground Resistance Measurements, Some of the. Curdts......760–7; disc. 767
Fuse as Fault Protection for Semiconductor Rectifiers, The Current-Limiting. Gutzwiller............. ....751–4; disc. 754

G

Gaging Plating Thickness, A System for. Myers, Waidelich..................................770–4
General Approach for Obtaining Transient Response by the Use of a Digital Computer, A. Lego, Sze..... 1031–6
Generalization of the Calculus of Finite Differences to Nonuniformly Spaced Variables, A. Kron.539–44
Generating Station, Electrical Features of Indian Point Nuclear Electric. Reimers................879–84
Generator, A Constant-Amplitude Random Function. Hellwarth..................................443–52
Generator, Analysis of Nonresonant Charging Circuit for Magnetic Pulse. Weinberg............271–7
Generator Instrumentation for Nuclear Power Plant with Analog Computer Vertification of Dynamic Action, Steam-. Lynch, Waite............690–6
Generator Reserve Requirement Study, The Use of a Digital Computer in a. Brown..............82–5
Generators, Spectrum Analysis of Random Noise. Polimerou..................................672–9
Generators Using Short-Time Memory Devices and Nonlinear Elements, The Design of Function. Revay, Ford..................................143–52
Ground Measurement, The Technique and Instrumentation of Low-Impedance. Duke, Smith...767–70
Ground Resistance Measurements, Some of the Fundamental Aspects of. Curdts.......760–7; disc. 767
Guarded Resistance Measuring Facility, A Precision. Wyeth, Higley, Shirk............471–5; disc. 475

H

Half-Wave Magnetic Amplifier, Triggering in the Reversible. McMurtrie, Ward..........598–605
Harmonic Magnetic Modulators, Design Criteria for Low-Level Second-. Kletsky............1013–19
Havana Radio System and Its Integration Into the Telephone Networks, The Miami-. Stiles, Hollins, Fruhner, Siddall..................................94–6
High Efficiency Push-Pull Magnetic Amplifier and Its Use as a D-C Shunt Motor Drive. Boyajian.545–50
High-Efficiency Push-Pull Magnetic Amplifiers with Transistors as Switched Rectifiers. Milnes....... ....327–30; disc. 330

High-Voltage 3-Phase Transformer, Measurement of Voltage Resulting From Single-Phase Switching of a. Dunkle, MacKenzie.........292–4; disc. 294
Horizon Equipment, Wide-Band Ultrahigh-Frequency Over-the-. Felsenheld, Havstad, Jatlow, LeVine, Pollack..........86–93
Horizon Links in Telecommunication Networks, Factors Affecting the Use of Over-the-. Parry..485–96
Hygrometer, Electric. Meiklejohn............302–05

I

Impedance and Return Loss Performance of Telephone Plant in Metropolitan Areas. Bogan..........257–61; disc. 261
Impedance of Cooling Fins, Thermal. Diebold, Luft..........739–45; disc. 745
Impedance Repeaters on Long Rural Telephone Lines, The Application of Negative-. Uthlaut.....230–4
Impedance Telephone Repeaters, Transistorized Negative-. Dimmer..........305–11
Improved 6-Channel Time Division Multiplex for Submarine Cable Telegraphy, An. Wilder....217–22
Impulse Voltage Dividers, Transient Response of. Fisher..........411–19; disc. 419
Impulse Waves with an Isolated Screen Room Installation, Measurements of Steep-Front. Miller, Wittibschlager..........262–70; disc. 270
Independent Telephone Company Areas: Transmission Considerations from the Direct Distance Dialing Standpoint, Dial Switching of Toll Circuits in. Petrie..........481–5
Indian Point Nuclear Electric Generating Station, Electrical Features of. Reimers..........879–84
Indicator With Elpak Translation Logic, An Electroluminescent Digital. Sack..........113–18
Inductance, Elimination of Magnetic Amplifier Control Circuit. Chandler, Downing.....550–6; disc. 556
Induction-Motor Drive, Transistor-Oscillator. Card..........531–5
Influence of Water Resistivity and Precipitation Rate Upon 60-Cycle Wet Flashover Voltage, The. (Committee Report)..........350–7; disc. 357
Information, Bits of. Zamanakos..........197–201
Information Theory to Digital Transmission Systems, Recent Progress in. Filipowsky..........848–55
Ink Recorders, Magnetic-Amplifier-Operated. Geyger..........457–71
Insertion Loss Filter Design Applied to Transistorized Carrier System. Winkler..........519–24
Installation, Measurements of Steep-Front Impulse Waves with an Isolated Screen Room. Miller, Wittibschlager..........262–70; disc. 270
Instrumentation for a Nuclear Power Plant with Analog Computer Verification of Dynamic Action, Steam-Generator. Lynch, Waite..........690–6
Instrumentation for High Performance Pressurized Water Reactor Power Plants, Main Coolant. Noyes..........683–90
Instrumentation, Modular Concepts in Reactor Control. Corkrell, Ryan, Magee..........696–9
Instrumentation of Low-Impedance Ground Measurement, The Technique and. Duke, Smith...767–70
(Instruments Electric) Hygrometer. Meiklejohn..........302–05
(Instruments) New Printing Demand Meter. Terry..........80–2
Instruments, On the Application of Zener Diodes to Expanded Scale. Corson..........535–9
Integral, The Numerical Evaluation of Expressions Involving Complete Elliptic. Grover.....496–502
Integrated Mobile Microwave Communications System for the Massachusetts Turnpike, An. Lowe..........703–06; disc. 706
Interference to Microwave Communication Services, Radar. Campbell..........717–22; disc. 722
Interoffice Trunking Facilities, Optimal Utilization and Extension of. Kalaba, Juncosa..........1998–1002; disc. 1002
Intertoll Trunks—Transmission Considerations, Nationwide Switching of. Wallman....223–9; disc. 229
Introducing Young Engineers to the Appreciation of Magnetic Amplifier Problems. Finzi......119–26
Ionosphere, Measurement of the Scattering Matrix with an Intervening. Brysk..........611–12
Iron-Cored Reactor Oscillatory Circuits, Subharmonics in. Mostafa, El-Karaksi..........104–13
Isolated Screen Room Installation, Measurements of Steep-Front Impulse Waves with an. Miller, Wittibschlager..........262–70; disc. 270

K

Key to the Continuing Control Renaissance, The Controlled Rectifier. Harnden....1006–12; disc. 1012

L

Laboratory Tool, The Operational Amplifier as a. Pfeiffer..........947–51; disc. 951
Linear Power Amplifiers Using Dynistors or Trinistors. Hierholzer..........892–8
Linearization of Dead Space. Jones..........836–8
Links to Telecommunication Networks, Factors Affecting the Use of Over-the-Horizon. Parry......485–96
Load Characteristics, Evaluation of Single Phase Metering Practices Based on Meter Performance and. Vanderleck..........727–38; disc. 738
Logic, An Electroluminescent Digital Indicator with Elpak Translation. Sack..........113–18
Logic for Applying Topological Methods to Electric Networks. Byerly, Long, King..657–65; disc. 665
Logical Networks, Matrix Analysis of. Schubert.10–13
Loops on Magnetic Amplifiers, Reactions of Bistable B-H. Morgan..........586–90
Loss Filter Design Applied to Transistorized Carrier System, Insertion. Winkler..........519–24
Loss Formula Studies, Digital Calculation of Network Functions Used in. Ferguson, Long, Rindt..........647–52; disc. 652
Loss Performance of Telephone Plant in Metropolitan Areas, Impedance and Return. Bogan..........257–61; disc. 261
Losses on Loaded Trunk Cables and Methods Taken to Improve Them, Study of Return. Speake..........201–04; disc. 204
Low Impedance Ground Measurement, The Technique and Instrumentation of. Duke, Smith.....767–70
Low-Level Second Haronic Magnetic Modulators, Design Criteria for. Kletsky..........1013–19

M

Magnetic Amplifier, A Fast-Response Full-Wave. Lynn..........37–41
Magnetic-Amplifier Analysis, Core-Reset Functions in. Feth:
  Part I. A Core Reset Function....503–09; disc. 509
  Part II. Determination of Amplifier Performance..........510–19
Magnetic Amplifier and Its Use as a D-C Shunt Motor Drive, High-Efficiency Push-Pull. Boyajian..........545–50
Magnetic Amplifier Bibliography—1951–1956. (Committee Report)..........613–27
Magnetic Amplifier Bibliography, 1957. (Committee Report)..........1051–7
Magnetic-Amplifier Commutating and Pulse-Width Encoding Circuit, A. Lucke..........884–92
Magnetic Amplifier Control Circuit Inductance, Elimination of. Chandler, Downing...550–6; disc. 556
Magnetic Amplifier Controlled Switched Transistors, Reversible-Polarity D-C Power Amplifier Using. Schmitz, Bernstein..........1058–60; disc. 1060
Magnetic Amplifier Cores, Proposed Standards for Core Test Methods for Toroidal. (Committee Report)..........524–31
Magnetic Amplifier Design. Anderson:
  Part I. Core..........160–7
  Part II. The Windings..........167–75
Magnetic Amplifier Design, A Comprehensive Study of. Hubbard, Bishop:
  Part I..........562–72
  Part II..........572–80; disc. 580
Magnetic Amplifier Driving One Phase of a Two-Phase Servo Motor, A Power Method of Measuring the Torque-Producing Output of a. Reisman, Bowman..........584–6
Magnetic-Amplifier-Operated Ink Recorders. Geyger..........457–71
Magnetic Amplifier Problems, Introducing Young Engineers to the Appreciation of. Finzi........119–26
Magnetic Amplifier, Triggering in the Reversible Half-Wave. McMurtrie, Ward..........598–605
(Magnetic Amplifiers) A New Control Amplifier Using a Saturable Current Transformer and a Switching Transistor. Morgan..........557–62; disc. 562
Magnetic Amplifiers, A-C Controlled. Lehtonen, Cronauer..........476–80
(Magnetic Amplifiers) Behavior of the Ferroresonant Series Circuit Containing a Square-Loop Reactor. Dennard..........903–11
(Magnetic Amplifiers) Block-Diagram Method of Analysis Applied to the Saturable Reactor. Hubbard..........57–64; disc. 65
Magnetic Amplifiers, On Feedback in. Finzi, Suozzi:
  Part I. Single Feedbacks.......1019–30 disc. 1030
Magnetic Amplifiers, Proposed Standard Terms and Definitions for. (Committee Report)..........429–31; disc. 431
Magnetic Amplifiers, Reactions of Bistable B-H Loops on. Morgan..........586–90
Magnetic Amplifiers, The Effective Feedback Factor of Self-Balancing. Geyger..........66–9
(Magnetic Amplifiers) The Transactor: A Self-Saturated Transformer. Rosenstein:
  Part I..........129–41; disc. 141
(Magnetic Amplifiers) Transistor-Oscillator Induction-Motor Drive. Card..........531–5
Magnetic Amplifiers Utilizing Square-Loop Core Material and Square-Wave Supply Voltage, Characteristics of. Britten..........590–7; disc. 597
Magnetic Amplifiers, Volt-Second Transfer Efficiency in Fast-Response. Pula:
  Part I..........861–7
Magnetic Amplifiers with Transistors as Switched Rectifiers, High-Efficiency Push-Pull. Milnes..........327–30; disc. 330
Magnetic Drum Components for High Storage Density. Hong..........667–72
Magnetic-Drum Storage System Considered for Use as a Common Sender in Nation-Wide Dialing, A. May..........5–10
Magnetic Field Strength in Oersteds Near Large Rectangular Conductors. Miller.....726–7; disc. 727
Magnetic Materials for Use in Ultrahigh-Temperature Electronic Transformers, An Experimental Study of. Harms..........181–4; disc. 184
Magnetic Modulator, A Triple-Action Positioning Controller Using a. Bullen..........785–7
Magnetic Modulators, Design Criteria for Low-Level Second-Harmonic. Kletsky..........1013–19
Magnetic Pulse Generator, Analysis of Nonresonant Charging Circuit for. Weinberg..........271–7
Magnetic Saturable-Core Timing Device. Lowrance..........393–7
Magnetics, Applications of Nonlinear. Storm..........380–8; disc. 388
Magnetometers, Self-Balancing Flux-Gate. Geyger..........213–16
Main Coolant Instrumentation for High-Performance Pressurized Water Reactor Power Plants. Noyes..........683–90

Parts Selection. The Economics of Component. Fuegel 13–16

Performance Objectives in a Telephone Communication System, A Basis for Transmission. MacAdam ....205–08; disc. 208

Performance of a Dual Cycle Boiling Water Reactor Nuclear Power Plant, Analog Computer Study of the Transient. Leiby........17–25

Performance of Class B Audio Amplifiers with Random Noise Signals. Usher........939–43

Performance of Telephone Plant in Metropolitan Areas, Impedance and Return Loss. Bogan........ ....257–61; disc. 261

Performance of the Primary Coolant System in a Water Reactor, Digital Calculation of Transient. Lewis 1036–43

Phase-Locked Oscillators, Transistor. Edwards, Golubjatnikov, Brady........1043–51

Philosophy of Applying Digital Computers to the Design of Electric Apparatus. Abetti, Cuthbertson Williams........367–77; disc. 377

Photographic Electronic Recorder, Digital and Pictorial. MacPherson, Sonderby........194–6

Pictorial Photographic Electronic Recorder, Digital and. McPherson, Sonderby........194–6

Picture Communication, Statistical Encoding for Test and. Michel........33–6

Pile Oscillator for the Ford Nuclear Reactor, The Design of a. Stone, Kerr........1003–6

Plan 55–A, Automatic Telegraph Switching System. Vernam........239–47

Plating Thickness, A System for Gaging. Myers, Waidelich........770-4

Polarity D-C Power Amplifier Using Magnetic-Amplifier Controlled Switched Transistors, Reversible-. Schmitz, Bernstein........1058–60; disc. 1060

Pole-Mounted Equipment, Stand-by Power for. Jamieson........774–8

Positioning Controller Using Magnetic Modulator, A Triple-Action. Bullen........785-7

Power Amplifier Using Magnetic-Amplifier Controlled Switched Transistors, Reversible-Polarity D-C. Schmitz, Bernstein........1058–60; disc. 1060

Power Amplifiers Using Dynistors or Trinistors, Linear. Hierholzer........892–8

Power for Pole-Mounted Equipment, Stand-by. Jamieson........774–8

Power Method of Measuring the Torque-Producing Output of a Magnetic Amplifier Driving One Phase of a Two-Phase Servo Motor, A. Reisman, Bowman 584–6

Power, Organic-Moderated Reactors for Central Station. Parkins, Weisner........985–93

Power Plant with Analog Computer Verification of Dynamic Action, Steam Generator Instrumentation for a Nuclear. Lynch, Waite........690–6

Power Plants, Main Coolant Instrumentation for High-Performance Pressurized Water Reactor. Noyes 683–90

Power Pool Operation Studies, Digital Computer Aids in. McIntyre, Blake, Clubb........652–7; disc. 657

Practical Mathematical Techniques, Some. Carter 295–302

Practice and the Economics of Applying Digital Computers to Engineering Problems, The. Abetti, Williams........331–41; disc. 341

Practices Based on Meter Performance and Load Characteristics, Evaluation of Single-Phase Metering Vanderleck........727–38; disc. 738

Preamplifier, A Stable Direct-Coupled Transistor Servo. DeSautels........943–7

Precipitation Rate Upon 60-Cycle Wet Flashover Voltage, The Influence of Water Resistivity and. Committee Report)........350–7; disc. 357

Precipitation Rectifiers, Automatic Control of Electrical. Van Hoesen, White, Hall........126–8

Precision, Guarded Resistance Measuring Facility, A. Wyeth, Higley, Shirk........471–5; disc. 475

Pressurized Water Reactor Power Plants, Main Coolant Instrumentation for High-Performance. Noyes 683–90

Primary Coolant System in a Water Reactor, Digital Calculation of Transient Performance of the. Lewis........1036–43

Printing Demand Meter, New. Terry........80–2

Private Branch Exchange, A New Small Crossbar Telephone System for. Abbott........911–18

Problems, Introducing Young Engineers to the Appreciation of Magnetic Amplifier. Finzi........119–26

Problems, The Practice and the Economics of Applying Digital Computers to Engineering. Abetti, Williams........331–41; disc. 341

Programming of Electronic Analog Computers, Matrix. Horn, Honnell........420–6; disc. 426

Progress in Applying Information Theory to Digital Transmission Systems, Recent. Filipowsky.848–55

Proposed Standard Terms and Definitions for Magnetic Amplifiers. (Committee Report)........ ....429–31; disc. 431

Proposed Standards for Core Test Methods for Toroidal Magnetic Amplifier Cores. (Committee Report).. 524–31

Protection for Semiconductor Rectifiers, The Current-Limiting Fuse as Fault. Gutzwiller........ ....751–4; disc. 754

Providence, R.I., Mechanization of Toll Switching at. Anderson, Thornton........954–60

Public Air–Ground Telephone Service Trial. Augustus 926–30

Pulse Generator, Analysis of Nonresonant Charging Circuit for Magnetic. Weinberg........271–7

Pulse-Width Encoding Circuit, A Magnetic-Amplifier Commutating and. Lucke........884–92

Push-Pull Magnetic Amplifier and Its Use as a D-C Shunt Motor Drive, High-Efficiency. Boyajian 545–50

Push-Pull Magnetic Amplifiers With Transistors as Switched Rectifiers, High-Efficiency. Milnes.. ....327–30; disc. 330

Q

Quadruplexer Allowing the Simultaneous Transmission of Two Complete Television Stations Using a Common Antenna, A. MacKimmie........787–91

R

Radar Interference to Microwave Communication Services. Campbell........717–22; disc. 722

Radio Attenuation at 11 Kmc and Some Implications Affecting Relay System Engineering. Hathaway, Evans........930–8; disc. 1061

(Radio Communication) A New Broad-Band Microwave Antenna System. Friis, May........97–100

(Radio Communication) An Integrated Mobile Microwave Communications System for the Massachusetts Turnpike. Lowe........703–06; disc. 706

(Radio Communication) Dial Telephone Service for Smith Island, an Isolated Community in Chesapeake Bay. Littleton........923–6

(Radio Communication) Factors Affecting the Use of Over-the-Horizon Links in Telecommunication Networks. Parry........485–96

(Radio Communication) Public Air-Ground Telephone Service Trial. Augustus....926–30
(Radio Communication) Radar Interference to Microwave Communication Services. Campbell....717–22; disc. 722
(Radio Communication) The Expansion of the Pacific Coast Microwave Network. Kuck....898–903
(Radio Communication) The Simultaneous Transmission of Television and Telephone Multiplex Over a Single Microwave Channel on the Trans-Canada TD-2 System. Curtis, Strahlendorf, Wade.185–90
(Radio Communication) Tropospheric-Scatter System Design. Yeh....707–16
(Radio Communication) Wide-Band Ultrahigh-Frequency Over-the-Horizon Equipment. Felsenheld, Havstad, Jatlow, LeVine, Pollack....86–93
Radio System and Its Integration into the Telephone Networks, The Miami-Havana. Stiles, Hollins, Fruhner, Siddall....94–6
Radio System for the United States Corps of Engineers, Willamette Valley. Pedersen, Marihart...401–06
Radio System for Toll Telephone Service, A 6,000-Megacycle. Kebby, Culbertson....969–79
(Rain Tests) The Influence of Water Resistivity and Precipitation Rate Upon 60-Cycle Wet Flashover Voltage. (Committee Report)...350–7; disc. 357
Random Function Generator, A Constant-Amplitude. Hellwarth....443–52
Random Noise Generators, Spectrum Analysis of. Polimerou....672–9
Random Noise Signals, Performance of Class B Audio Amplifiers with. Usher....939–43
Random Selectors, Spinning Disk. Roberts....755–60
Rate Studies on Silicon Rectifiers, Failure-. Bechtold, Hanks....49–56
Reactance Modulator, The Diode. Montgomery.980–3
Reactions of Bistable B-H Loops on Magnetic Amplifiers. Morgan....586–90
Reactor, An Electronic Feedwater Control System for the Experimental Boiling Water. Morse, Brey....679–83
Reactor, Behavior of the Ferroresonant Series Circuit Containing a Square-Loop. Dennard.....903–11
Reactor, Block-Diagram Method of Analysis Applied to the Saturable. Hubbard....57–64; disc. 65
Reactor Control Instrumentation, Modular Concepts in. Cockrell, Ryan, Magee....696–9
Reactor, Digital Calculation of Transient Performance of the Primary Coolant System in a Water. Lewis....1036–43
Reactor Nuclear Power Plant, Analog Computer Study of the Transient Performance of a Dual Cycle Boiling Water. Leiby....17–25
Reactor Oscillatory Circuits, Subharmonics in Iron-Cored. Mostafa, El-Karaksi....104–13
Reactor Power Plants, Main Coolant Instrumentation for High Performance Pressurized Water. Noyes....683–90
Reactors for Central Station Power, Organic-Moderated. Parkins, Weisner....985–93
Reactors for Semiconductor Rectifiers, Current-Balancing. Dortort....452–6; disc. 456
Recent Progress in Applying Information Theory to Digital Transmission Systems. Filipowsky.848–55
Recorder, Digital and Pictorial Photographic Electronic. McPherson, Sonderby....194–6
Recorders, Magnetic-Amplifier-Operated Ink. Geyger....457–71
(Recording and Controlling Instruments) A Triple-Action Positioning Controller Using a Magnetic Modulator. Bullen....785–7
Rectangular Conductors, Magnetic Field Strength in Oersteds Near Large. Miller.....726–7; disc. 727
Rectifier: Key to the Continuing Control Renaissance, The Controlled. Harnden....1006–12; disc. 1012
Rectifiers, Automatic Control of Electrical Precipitation. VanHoesen, White, Hall....126–8
Rectifiers, Current-Balancing Reactors for Semiconductor. Dortort....452–6; disc. 456
Rectifiers, Failure-Rate Studies on Silicon. Bechtold, Hanks....49–56
Rectifiers from Oxide Masked Diffused Structures, Silicon-Controlled. Aldrich, Holonyak.....952–4
Rectifiers, Forward Current Surge Failure in Semiconductor. Gentry....746–50; disc. 754
Rectifiers, High-Efficiency Push-Pull Magnetic Amplifiers with Transistors as Switched. Milnes....327–30; disc. 330
Rectifiers, The Current Limiting Fuse as Fault Protection for Semiconductor. Gutzwiller....751–4; disc. 754
Redundancy Networks, The Analysis of. Moskowitz....627–32
Relay Scanning Design Technique Generates High Accuracy and Speed in Analog-to-Digital Transducer Measurements. Kay....248–50
Relay System Engineering, Radio Attenuation at 11 Kmc and Some Implications Affecting. Hathaway, Evans....930–8; disc. 1061
Reliable Stochastic Sequential Switching Circuits. Mullin....606–11
Renaissance, The Controlled Rectifier: Key to the Continuing Control. Harnden....1006–12; disc. 1012
Repeater for Military Use, A Frequency-Converting Telephone Carrier. Goltsos, Johnston, Anderson....432–6
Repeater for Use with the 45BN Cable Carrier System, A Transistorized. Babin, Fish....41–9
Repeaters on Long Rural Telephone Lines, The Application of Negative-Impedance. Uthlaut......230–4
Repeaters, Transistorized Negative-Impedance Telephone. Dimmer....305–11
Requirement Study, The Use of a Digital Computer in a Generator Reserve. Brown....82–5
Research in Communications, Operations. Harris, Hauptschein, Schwartz....633–7; disc. 637
Reserve Requirement Study, The Use of a Digital Computer in a Generator. Brown....82–5
Reset Functions in Magnetic-Amplifier Analysis, Core-. Feth:
  Part I. A Core Reset Function....503–09; disc. 509
  Part II. Determination of Amplifier Performance....510–19
Resistance Measuring Facility, A Precision, Guarded. Wyeth, Higley, Shirk....471–5; disc. 475
Resistivity and Precipitation Rate Upon 60-Cycle Wet Flashover Voltage, The Influence of Water. (Committee Report)....350–7; disc. 357
Response of Impulse Voltage Dividers, Transient. Fisher....411–19; disc. 419
Response Time of Thermal Converters, The Definition and Measurement of the Time Constant and. Hermach....277–82; disc. 282
Return Losses on Loaded Trunk Cables and Methods Taken to Improve Them, Study of. Speake....201–04; disc. 204
Reversible Half-Wave Magnetic Amplifier, Triggering in the. McMurtrie, Ward....598–605
Reversible-Polarity D-C Power Amplifier Using Magnetic-Amplifier Controlled Switched Transistors. Schmitz, Bernstein....1058–60; disc. 1060
Rural Telephone Lines, The Application of Negative Impedance Repeaters on Long. Uthlaut....230–4

S

Safety System, Variation of the Trip Point in the ORNL-Type. Cockrell, Ricker....699–703
SAGE Data System Considerations. Enticknap, Schuster....824–32
SAGE Data Systems, Communication Channels for. James....838–43
SAGE Data Terminals. Soffel, Spack....872–9
Saturable-Core Timing Device, Magnetic. Lowrance....393–7
Saturable Current Transformer and a Switching Transistor, A New Control Amplifier Using a. Morgan....557–62; disc. 562
Saturable Reactor, Block-Diagram Method of Analysis Applied to the. Hubbard....57–64; disc. 65
Scale Instruments, On the Application of Zener Diodes to Expanded. Corson....535–9
Scanning Design Technique Generates High Accuracy and Speed in Analog-to-Digital Transducer Measurements, Relay. Kay....248–50
Scatter System Design, Tropospheric-. Yeh....707–16
Scattering Matrix with an Intervening Ionosphere, Measurement of the. Brysk....611–12
School Teaching, Television Systems for In-. Kraus....406–11
Screen Room Installation, Measurements of Steep-Front Impulse Waves With an Isolated. Miller, Wittibschlager....262–70; disc. 270
Second Harmonic Magnetic Modulators, Design Criteria for Low-Level. Kletsky....1013–19
Selection, The Economics of Component Parts. Fuegel....13–16
Selectors, Spinning Disk Random. Roberts....755–60
Self-Balancing Flux-Gate Magnetometers. Geyger....213–16
Self-Balancing Magnetic Amplifiers, The Effective Feedback Factor of. Geyger....66–9
Self-Saturated Transformer, The Transactor: A. Rosenstein:
  Part I....129–41; disc. 141
(Semiconductor Metallic Rectifiers) Linear Power Amplifiers Using Dynistors or Trinistors. Hierholzer....892–8
(Semiconductor Metallic Rectifiers) The Controlled Rectifier: Key to the Continuing Control Renaissance. Harnden....1006–12; disc. 1012
(Semiconductor Metallic Rectifiers) Theory of Transient Build-up in Avalanche Transistors. Shockley, Gibbons....993–8
Semiconductor Rectifiers, Current-Balancing Reactors for. Dortort....452–6; disc. 456
Semiconductor Rectifiers, Forward Current Surge Failure in. Gentry....746–50; disc. 754
Semiconductor Rectifiers, The Current Limiting Fuse as Fault Protection for. Gutzwiller....751–4; disc. 754
Serial-Type Digital Data Systems, An Analog Computer Study of the Transient Behavior and Stability Characteristics of. Elgerd......358–66; disc. 366
Series Circuit Containing a Square-Loop Reactor, Behavior of the Ferroresonant. Dennard.....903–11
Servo Motor, A Power Method of Measuring the Torque-Producing Output of a Magnetic Amplifier Driving One Phase of a Two-Phase. Reisman, Bowman....584–6
Servo Preamplifier, A Stable Direct-Coupled Transistor. DeSautels....943–7
Set, Data Transmission Testing. Boughtwood, Christie....101–04
Shifting Counters. Eldert, Gray, Gurk, Rubinoff..70–4
Short-Time Memory Devices and Nonlinear Elements, The Design of Function Generators Using. Revay, Ford....143–52
Shunt Motor Drive, High Efficiency Push-Pull Magnetic Amplifier and Its Use as a D-C. Boyajian..545–50
Signals, Performance of Class B Audio Amplifiers with Random Noise. Usher....939–43
Silicon-Controlled Rectifiers from Oxide Masked Diffused Structures. Aldrich, Holonyak.......952–4
Silicon Rectifiers, Failure-Rate Studies on. Bechtold, Hanks....49–56
Simultaneous Transmission of Television and Telephone Multiplex Over a Single Microwave Channel on the Trans-Canada TD-2 System, The. Curtis, Strahlendorf, Wade....185–90
Simultaneous Transmission of Two Complete Television Stations Using a Common Antenna, A Quadruplexer Allowing the. MacKimmie........787–91
Single Phase Metering Practices Based on Meter Performance and Load Characteristics, Evaluation of. Vanderleck....727–38; disc. 738
Single-Phase Switching of a High-Voltage 3-Phase Transformer, Measurement of Voltage Resulting From. Dunkle, MacKenzie.....292–4; disc. 294
Six-Channel Time Division Multiplex for Submarine Cable Telegraphy, An Improved. Wilder..217–22
60-Cycle Wet Flashover Voltage, The Influence of Water Resistivity and Precipitation Rate Upon. (Committee Report)....350–7; disc. 357
6,000-Megacycle Radio System for Toll Telephone Service, A. Kebby, Culbertson....969–79
Smith Island, an Isolated Community in Chesapeake Bay, Dial Telephone Service for. Littleton..923–6
Some of the Fundamental Aspects of Ground Resistance Measurements. Curdts....760–7; disc. 767
Some Practical Mathematical Techniques. Carter....295–302
Space, Linearization of Dead. Jones....836–8
Spaced Variables, A Generalization of the Calculus of Finite Differences to Nonuniformly. Kron.539–44
Spectrum Analysis of Random Noise Generators. Polimerou....672–9
Spinning Disk Random Selectors. Roberts....755–60
Square-Loop Core Material and Square-Wave Supply Voltage, Characteristics of Magnetic Amplifiers Utilizing. Britten....590–7; disc. 597
Square-Loop Reactor, Behavior of the Ferroresonant Series Circuit Containing a. Dennard.....903–11
Stability, An Electric Circuit Theory Approach to Finite Difference. Karplus....210–13
Stability Characteristics of Serial-Type Digital Data Systems, An Analog Computer Study of the Transient Behavior and. Elgerd.....358–66; disc. 366
Stabilized Bridged-T Oscillator, An Amplitude-. Enslein....75–9
Stabilized D-C Differential Transistor Amplifier, A. Depian, Smith....157–9
Stable Direct-Coupled Transistor Servo Preamplifier, A. DeSautels....943–7
Standard Terms and Definitions for Magnetic Amplifiers, Proposed. (Committee Report)....429–31; disc. 431
Standards for Core Test Methods for Toroidal Magnetic Amplifier Cores, Proposed. (Committee Report)....524–31
Stand-by Power for Pole-Mounted Equipment. Jamieson....774–8
Statistical Encoding for Text and Picture Communication. Michel....33–6
Steam-Generator Instrumentation for a Nuclear Power Plant with Analog Computer Verification of Dynamic Action. Lynch, Waite....690–6
Steep-Front Impulse Waves with an Isolated Screen Room Installation, Measurements of. Miller, Wittibschlager....262–70; disc. 270
Stochastic Sequential Switching Circuits, Reliable. Mullin....606–11
Storage Density, Magnetic Drum Components for High. Hong....667–72
Storage System Considered for Use as a Common Sender in Nation-Wide Dialing, A Magnetic-Drum. May....5–10
Structures, Silicon Controlled Rectifiers from Oxide Masked Diffused. Aldrich, Holonyak......952–4
Studies on Silicon Rectifiers, Failure-Rate. Bechtold, Hanks....49–56
Study of a Binary Code, An Experimental. Peterson....388–92; disc. 392
Study of Magnetic-Amplifier Design, A Comprehensive. Hubbard, Bishop:
  Part I....562–72
  Part II....572–80; disc. 580

Vol,
Pt. 1
195

Study of Magnetic Materials for Use in Ultrahigh-Temperature Electronic Transformers, An Experimental. Harms....181–4; disc. 184
Study of Return Losses on Loaded Trunk Cables and Methods Taken to Improve Them. Speake....201–04; disc. 204
Study of the Transient Performance of a Dual Cycle Boiling Water Reactor Nuclear Power Plant, Analog Computer. Leiby....17–25
Study, The Use of a Digital Computer in a Generator Reserve Requirement. Brown....82–5
Subharmonics in Iron-Cored Reactor Oscillatory Circuits. Mostafa, El-Karaksi....104–13
Submarine Cable Telegraphy, An Improved 6-Channel Time Division Multiplex for. Wilder....217–22
Subset for Data Transmission Over Telephone Lines, A Frequency Modulation Digital. Weber....867–72
Surge Failure in Semiconductor Rectifiers, Forward Current. Gentry....746–50; disc. 754
Surge Measurement Errors Introduced by Coaxial Cables. Park....343–7; disc. 347
Switched Rectifiers, High-Efficiency Push-Pull Magnetic Amplifiers with Transistors as. Milnes....327–30; disc. 330
Switched Transistors, Reversible-Polarity D-C Power Amplifier Using Magnetic-Amplifier Controlled. Schmitz, Bernstein....1058–60; disc. 1060
Switching at Providence, R.I., Mechanization of Toll. Anderson, Thornton....954–60
Switching Circuits, Minimization of Components in Electronic. Beatson....283–91; disc. 291
Switching Circuits, Reliable Stochastic Sequential. Mullin....606–11
Switching of a High-Voltage 3-Phase Transformer, Measurement of Voltage Resulting From Single-Phase Dunkle, MacKenzie....292–4; disc. 294
Switching of Interoll Trunks—Transmission Considerations, Nationwide. Wallman....223–9; disc. 229
Switching of Toll Circuits, in Independent Telephone Company Areas: Transmission Considerations from the Direct Distance Dialing Standpoint, Dial. Petrie....481–5
Switching System Plan 55-A, Automatic Telegraph. Vernam....239–47
Switching Transistor, A New Control Amplifier Using a Saturable Current Transformer and a. Morgan....557–62; disc. 562
Symmetric Channel, On Coding for the Binary. Fontaine, Peterson....638–46; disc. 646
Symmetric Decision Feedback Systems, Binary. Harris, Morgan....436–43
Synchronized Clocks for Data Transmission. Edson, Flavin, Perry....832–6
Synthesis by Means of Computers, Direct System. Clymer....798–806

Transistor Servo Preamplifier, A Stable Direct Coupled. DeSautels....943–7
Transistorized Carrier System, Insertion Loss Filter Design Applied to. Winkler....519–24
Transistorized Compandor, A. Perkins, Perreault, Perkins....791–7
Transistorized Negative-Impedance Telephone Repeaters. Dimmer....305–11
Transistorized Repeater for Use with the 45BN Cable Carrier System, A. Babin, Fish....41–9
Transistors as Switched Rectifiers, High-Efficiency Push-Pull Magnetic Amplifiers with. Milnes....327–30; disc. 330
Transistors, Reversible-Polarity D-C Power Amplifier Using Magnetic Amplifier Controlled Switched. Schmitz, Bernstein....1058–60, disc. 1060
Transistors, Theory of Transient Build-up in Avalanche. Shockley, Gibbons....993–8
Translation Logic, An Electroluminescent Digital Indicator with Elpak. Sack....113–18
Transmission Considerations from the Direct Distance Dialing Standpoint, Dial Switching of Toll Circuits in Independent Telephone Company Areas:. Petrie....481–5
Transmission Considerations, Nationwide Switching of Intertoll Trunks—. Wallman....223–9; disc. 229
Transmission of Television and Telephone Multiplex Over a Single Microwave Channel on the Trans-Canada TD-2 System, The Simultaneous. Curtis, Strahlendorf, Wade....185–90
Transmission of Two Complete Television Stations Using a Common Antenna, A Quadruplexer Allowing the Simultaneous. MacKimmie....787–91
Transmission Over Telephone Lines, A Frequency Modulation Digital Subset for Data. Weber....867–72
Transmission Performance Objectives in a Telephone Communication System, A Basis for. MacAdam....205–08; disc. 208
Transmission, Synchronized Clocks for Data. Edson, Flavin, Perry....832–6
Transmission Systems, Recent Progress in Applying Information Theory to Digital. Filipowsky....848–55

Transmission Testing Set, Data. Boughtwood, Christie 101–04
Transmission with Error Checking, Optimum Block Length for Data. Wood........ 855–61
Triggering in the Reversible Half-Wave Magnetic Amplifier. McMurtrie, Ward........ 598–605
Trinistors, Linear Power Amplifiers Using Dynistors or. Hierholzer........ 892–8
Trip Point in the ORNL-Type Safety System, Variation of the. Cockrell, Ricker........ 699–703
Triple-Action Positioning Controller Using a Magnetic Modulator, A. Bullen........ 785–7
Tropospheric-Scatter System Design. Yeh........ 707–16
Trunk Cables and Methods Taken to Improve Them, Study of Return Losses on Loaded. Speake........ 201–04; disc. 204
Trunking Facilities, Optimal Utilization and Extension of Interoffice. Kalaba, Juncosa........ 998–1002; disc. 1002
Trunks—Transmission Considerations, Nationwide Switching of Intertoll. Wallman. 223–9; disc. 229
Type OJ Carrier Telephone System. Coy, Kelsey, Nicholls........ 810–17

U

Ultrahigh-Frequency Over-the-Horizon Equipment, Wide-Band. Felsenheld, Havstad, Jatlow, Levine, Pollack........ 86–93
Ultrahigh-Temperature Electronic Transformers, An Experimental Study of Magnetic Materials for Use in. Harms........ 181–4; disc. 184
United States Corps of Engineers, Willamette Valley Radio System for the. Pedersen, Marihart. 401–06
Use of a Digital Computer in a Generator Reserve Requirement Study, The. Brown........ 82–5
Utilization and Extension of Interoffice Trunking Facilities, Optimal. Kalaba, Juncosa........ 998–1002; disc. 1002

V

Variables, A Generalization of the Calculus of Finite Differences to Nonuniformly Spaced. Kron........ 539–44
Variation of the Trip Point in the ORNL-Type Safety System. Cockrell, Ricker........ 699–703
Video Testing Techniques in Television Broadcasting. Ste-Marie........ 26–33
Volt-Second Transfer Efficiency in Fast-Response Magnetic Amplifiers. Pula:
  Part I........ 861–7
Voltage, Characteristics of Magnetic Amplifiers Utilizing Square-Loop Core Material and Square-Wave Supply. Britten........ 590–7; disc. 597
Voltage Dividers, Transient Response of Impulse. Fisher........ 411–19; disc. 419
Voltage Resulting From Single-Phase Switching of a High-Voltage 3-Phase Transformer, Measurement of. Dunkle, MacKenzie........ 292–4; disc. 294
Voltage, The Influence of Water Resistivity and Precipitation Rate Upon 60-Cycle Wet Flashover. (Committee Report)........ 350–7; disc. 357

W

Water Reactor, Digital Calculation of Transient Performance of the Primary Coolant System in a. Lewis........ 1036–43
Water Reactor Nuclear Power Plant, Analog Computer Study of the Transient Performance of a Dual Cycle Boiling. Leiby........ 17–25
Water Reactor Power Plants, Main Coolant Instrumentation for High Performance Pressurized. Noyes........ 683–90
Water Resistivity and Precipitation Rate Upon 60-Cycle Wet Flashover Voltage, The Influence of. (Committee Report)........ 350–7; disc. 357
Watt-Hour Meter for Two Phases of a 4-Wire Y 3-Phase System. McQuarrie........ 152–5; disc. 155
Waves with an Isolated Screen Room Installation, Measurements of Steep-Front Impulse. Miller, Wittibschlager........ 262–70; disc. 270
Wet Flashover Voltage, The Influence of Water Resistivity and Precipitation Rate Upon 60-Cycle. (Committee Report)........ 350–7; disc. 357
Wide-Band Ultrahigh-Frequency Over-the-Horizon Equipment. Felsenheld, Havstad, Jatlow, LeVine, Pollack........ 86–93
Willamette Valley Radio System for the United States Corps of Engineers. Pedersen, Marihart... 401–06
(Wire Communications) A Basis for Transmission Performance Objectives in a Telephone Communication System. MacAdam........ 205–08; disc. 208
(Wire Communications) A Frequency-Converting Telephone Carrier Repeater for Military Use. Goltsos, Johnston, Anderson........ 432–6
(Wire Communications) A New Method of Frequency Error Correction in Carrier Systems. Stachiewicz........ 175–80
(Wire Communications) A Transistorized Compandor. Perkins, Perreault, Perkins........ 791–7
(Wire Communications) A Transistorized Repeater for Use with the 45BN Cable Carrier System. Babin, Fish........ 41–9
(Wire Communications) Determination of the Least First Cost of a Cable-Carrier System. Krzyczkowski........ 778–82; disc. 782
(Wire Communications) Dial Switching of Toll Circuits in Independent Telephone Company Areas: Transmission Considerations from the Direct Distance Dialing Standpoint. Petrie........ 481–5
(Wire Communications) Impedance and Return Loss Performance of Telephone Plant in Metropolitan Areas. Bogan........ 257–61; disc. 261
(Wire Communications) Insertion Loss Filter Design Applied to Transistorized Carrier System. Winkler........ 519–24
(Wire Communications) Stand-by Power for Pole-Mounted Equipment. Jamieson........ 774–8
(Wire Communications) Study of Return Losses on Loaded Trunk Cables and Methods Taken to Improve Them. Speake........ 201–04; disc. 204
(Wire Communications) The Application of Negative-Impedance Repeaters on Long Rural Telephone Lines. Uthlaut........ 230–4
(Wire Communications) The ON/K Carrier System. Masters........ 806–10
(Wire Communications) Transistorized Negative-Impedance Telephone Repeaters. Dimmer... 305–11
(Wire Communications) Type OJ Carrier Telephone System. Coy, Kelsey, Nicholls........ 810–17

Y

Y Three-Phase System, Watt-Hour Meter for Two Phases of a 4-Wire. McQuarrie.. 152–5; disc. 155

Z

Zener Diodes to Expanded Scale Instruments, On the Application of. Corson........ 535–9

A Differentiator for A-C Computers

WHEELER X. JOHNSON
ASSOCIATE MEMBER AIEE

THIS PAPER describes an electronic circuit which differentiates, with respect to time, information represented by the amplitude modulation of an a-c carrier wave. A circuit of this type is useful in a-c fire-control computing systems where rate information must be obtained from positional input data. In any fire-control computer, the choice of the particular type of differentiator to be used depends upon the form of the input data. If these data are in the form of d-c signals, accurate electronic differentiating circuits are available. If they are in the form of a-c signals a positional servo coupled to an a-c tachometer is usually used[1] (especially for rectangular co-ordinate fire-control systems). The accuracy of servo differentiators, however, is inadequate for many applications. The electronic circuit to be described offers a means of obtaining, for an a-c fire-control computing system, more accurate differentiation than has so far been obtained using servo differentiators. Basically, the circuit described is a modification of a well-known d-c differentiator circuit which utilizes a Miller integrator in a feedback path, achieving differentiation by the implicit function technique.[2] A magnetically keyed demodulator[3,4] has been incorporated into the design so that the d-c circuit can be used in an a-c computing system. This demodulator circuit has excellent linearity characteristics and a wide operating range, making the electronic differentiator design feasible for many applications.

To confirm the validity of the theoretical considerations outlined in this paper, an experimental differentiator unit for a typical fire-control application has been designed and built. This unit employs the afore-mentioned magnetic demodulator, and magnetic circuits in the stabilization circuit of the integrator amplifier. The results of the tests which were conducted on this unit indicate that an accuracy of ±0.1% can be obtained with satisfactory over-all dynamic performance. To the author's knowledge, the best accuracy obtained using servo differentiators for this application has been about ±1%. The ±0.1% figure therefore represents an improvement in accuracy by a factor of 10.

Description

Fig. 1 is a block diagram of the differentiator circuit showing the interrelation of its four principal components; a d-c integrator, a sampling-type demodulator, a d-c amplifier, and a positional servo. The demodulator and the servo provide the necessary coupling between the a-c system and the d-c differentiator circuit. The demodulator serves two purposes. It converts the input signal from alternating to direct current, and performs the necessary summing of the a-c input signal and the d-c integrator output. The positional servo is of standard design and is used solely to modulate the d-c output of the electronic portion of the differentiator circuit.

In using a servo as a modulator rather than a differentiator, some of the difficulties engendered by the nonlinear characteristics of the feedback potentiometer are not encountered. (In the servo differentiator design, the positional error is differentiated in the same manner as the input signal, which means that the important characteristic of the feedback potentiometer is not its deviation from linearity but rather the slope of linearity error. The fluctuations in the output caused by potentiometer nonlinearity can be made arbitrarily small by reducing the bandwidth of the servo. In reducing the bandwidth, however, the dynamic performance of the system suffers. In many applications, no satisfactory compromise can be found between these two conflicting requirements.) Detailed information on the design of positional servos may be obtained from references 5 and 6.

A block diagram of the d-c portion of the differentiator circuit is shown in Fig. 2. Using the implicit function technique, differentiation is obtained by placing an integrator in the feedback path. If the integrator is assumed to be perfect, the transfer function for the simplified circuit is

$$W(s)=\frac{E_o}{E_i}=\frac{s}{\frac{s}{K_{a1}}+1} \tag{1}$$

The circuit therefore, acts as a differentiator having a bandwidth which depends directly on the gain, K_{a1}, of the d-c amplifier. In a practical system, the determination of the bandwidth is usually based on a compromise between two conflicting requirements, the need for maximum filtering of input noise components, and the need for a rapid settling time for large step inputs. In the experimental differentiator unit, this problem is resolved by using two modes of operation. Under normal operation, when the error signals are small, the bandwidth is approximately a half-cycle per second. When large step input signals occur, however, silicon diodes in the circuit act to increase the bandwidth so that rapid settling time is obtained. When the magnitude of the error voltage is reduced to within its normal limits, the bandwidth reverts to its normal value.

The transfer function of the differentiator circuit based on the more exact block diagram representation, which is shown in Fig. 1, is

$$W(s)=\frac{K_dK_{a1}e^{-\frac{\pi}{\omega_c}s}[RC(K_{a2}+1)s+1]}{RC(K_{a2}+1)s+1+K_dK_{a1}K_{a2}e^{-\frac{\pi}{\omega_c}s}} \tag{2}$$

where ω_c is defined as the computing system carrier frequency. In a practical differentiating circuit the parameters are so chosen that

$K_{a1}>>1$
$K_{a2}>>1$
$K_d\cong 1$
$\omega_c>>$maximum signal frequency

Introducing these relations, the transfer function can be approximated as

$$W(s)\cong\frac{RCs+\left(\frac{1}{K_{a2}}\right)}{\frac{RC}{K_{a1}}s+1} \tag{3}$$

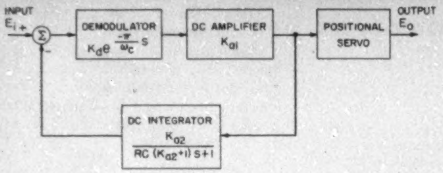
If the gain, K_{a2}, were infinite, equation 3 would be identical in form with equation 1, and the device would act as a perfect differentiator with a finite bandwidth. Because the gain must be finite in a prac-

---

Paper 57-193, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 21–25, 1957. Manuscript submitted July 5, 1956; made available for printing June 17, 1957.

WHEELER X. JOHNSON is with the Radio Corporation of America, Waltham, Mass.

This report is based on a Master of Science Thesis submitted by the author to the Massachusetts Institute of Technology.[14] The author wishes to acknowledge the contributions, made during the course of the thesis research, by Paul R. Johannessen, Dr. John C. Simons, Jr., and Dr. George C. Newton of the Servomechanisms Laboratory. The research reported in this document was supported jointly by the Departments of Army, Navy, and Air Force under Air Force Contract No. *AF 19(122)-458* with Lincoln Laboratory, MIT, and executed under subcontract by the MIT Servomechanisms Laboratory. It is published for technical information only and does not represent recommendations or conclusions of the sponsoring agencies.



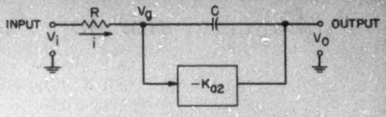


Fig. 3. Miller integrator

Fig. 1 (left). Differentiator block diagram

tical system the differentiation can never be perfect, and the dynamic term in the numerator will introduce an error which will increase with time. This error derives from the imperfect performance of the integrator, and will be discussed at more length in a later section.

In general, the performance, of the differentiator circuit depends upon three factors: the integrator accuracy, the amount of drift, and the amount of internal noise. An estimate of the influence of the first two of these factors can be made by analysis from the theoretical considerations discussed in the section on "Error Considerations." The third must be determined by actual measurement. Of the four principal components of the differentiator circuit, the integrator and the demodulator are of particular interest and are therefore discussed in some detail in the following sections. The remaining two, the d-c amplifier and the positional servo, are of standard design and will not be discussed further.

Integrator Circuit

D-c integrators of the Miller type have been developed to a high degree of accuracy for computing purposes.[7-10] A circuit of this type is used in the experimental electronic differentiator. A block diagram of this circuit is shown in Fig. 3. For the purposes of this report, the circuit transfer function can be assumed to be

$$W_I(s)=\frac{V_o(s)}{V_i(s)}=\frac{K_{a2}}{RC(K_{a2}+1)s+1} \qquad (4)$$

To minimize drift, the gain, K_{a2}, is usually obtained by using a "chopper-stabilized" d-c amplifier.[11] If there are only low frequency components present in the integrator input signal, as is the case in most fire-control problems, the gain can be obtained either by using an a-c amplifier alone or by cascading a-c and d-c amplifiers. This latter arrangement, used in the experimental differentiator unit, is shown in Fig. 4. Because the modulation-demodulation process introduces a time delay into the integrator loop, the use of suitable compensating networks is necessary to obtain stable operation. A stage of d-c amplification is included in order to make full use of the noise-rejection properties of the demodulator and of the compensating networks.

The two silicon diodes and the 22,000-ohm resistor, which are placed in parallel with the 1-megohm integrating resistor, as shown in Fig. 4, reduce the settling time of the differentiator circuit following large step input signals. When a step occurs, the error signal is large; hence, the integrator input signal is also large. As long as the magnitude of the integrator input signal exceeds the "Zener" voltage of the silicon diodes, the diode impedance is very low and the integrating resistance is 22,000 ohms instead of 1 megohm. The integrator time constant, and hence the settling time of the differentiator circuit, is correspondingly reduced. When the magnitude of the integrator input signal drops below the the magnitude of the diode Zener voltage, the diode impedance becomes very high (on the order of 100 megohms) and the integrating resistance again becomes 1 megohm.

The Magnetic Circuits

The experimental differentiator unit utilizes a magnetic modulator and two magnetic demodulators. One demodulator is located in the main loop. The modulator and the second demodulator are employed at the input and the output of the a-c amplifier used in the integrator; see Figs. 1 and 4. The basic mode of operation of these two types of magnetic circuit is similar. Each circuit embodies a gating section, which acts as a switch between the input and output terminals and a driving section, which controls the operation of the switch.

DEMODULATOR

The operation of the demodulator can best be analyzed by considering the basic circuit shown in Fig. 5. The driving section of the circuit causes the switch to close for a short period of time during the positive peaks of the a-c reference voltage wave form. While the switch is closed, the output capacitor, C_o, charges to the peak value of the input voltage. At all other times, the switch is open and the capacitor voltage remains constant. The output, therefore, is a direct voltage having an amplitude equal to the peak amplitude of the a-c input voltage.

The demodulator circuit is shown in Fig. 6. The gating section acts as the "switch" which is closed when the two silicon diodes are conducting current. Conduction is controlled by a series of

pulses, produced by the driving section[12] and appearing on the secondary windings of reactor II. When a pulse appears the diodes conduct current, and the bias capacitors C_1 and C_2 are charged with the polarity shown in Fig. 6. During the interval between pulses, the charge on the bias capacitors prevents the diodes from conducting. The pulses are timed to occur at the positive peaks of the a-c input voltage waveform so that the desired switching action is obtained.

The demodulator cannot distinguish between a-c and d-c input voltages because it is a sampling device that investigates the magnitude of the input signal at only one point in the a-c voltage wave form. If an a-c signal and a d-c signal are superimposed at the demodulator input, the output is a d-c signal equal to the sum (or the difference) of the two input signals. This summing ability of the demodulator is utilized in the differentiator circuit to obtain the difference between the a-c input signal and the d-c output of the integrator circuit.

The sampling action has the disadvantage that it makes the demodulator very sensitive to high frequency noise components which may appear on the crests of the input signal wave form. This is not a serious difficulty in the differentiator circuit, however, because the objectionable high-frequency noise components can be easily eliminated by suitable filtering of the signal before it reaches the demodulator.

MODULATOR

The basic modulator circuit is shown in Fig. 7. Here, the switch arm changes position every half-cycle of the a-c reference voltage wave, remaining in one position for a full half-cycle. The output is thereby connected on alternate half-cycles to the input and to ground, producing a square wave which has a peak-to-peak amplitude equal to the amplitude of the d-c input voltage, and the same frequency and phase as the a-c reference voltage.

A schematic diagram of the modulator circuit is shown in Fig. 8. The transistor circuit in the driving section[13] produces a square wave on the secondary windings of transformer T_1. When the polarity is as indicated in Fig. 8, diodes D_2 and D_3 conduct current, and diodes D_1 and D_4 are held cut off. Under these conditions, and output terminal is effectively grounded. When the square wave reverses polarity, the pattern of conduction in the diodes is also reversed, and the output terminal is effectively connected to the input terminal. In operation the square wave reverses polarity every half-cycle of the reference voltage, producing the desired switching action.

Error Considerations

INTEGRATOR ACCURACY

The magnitude of the error in the ouput of the differentiator depends primarily on the accuracy of the Miller integrator. The differentiator output (which serves as the input to the integrator) approximates a step when a ramp input signal is applied. The fractional error (Fractional Error=|Correct Value−Actual Value|/Correct Value) in the integrator output for a step input can be determined from the following expression:[10]

$$\text{Fractional Error} = \frac{1}{2}\,\frac{t}{RC\,K_{a2}} \qquad (5)$$

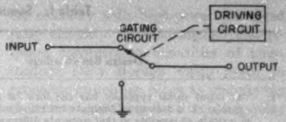

Fig. 7. Basic keyed modulator circuit

The error is smallest when the gain, K_{a2}, is high and the computing time, t, is short.

DRIFT

In using the electronic differentiator circuit as part of an a-c computing system, it is normally desirable to calibrate the circuit so that for a zero rate input, the output voltage is also zero. During subsequent operation, variations in the characteristics of the circuit components may cause the calibration to change so that the output voltage is no longer zero for a zero rate input. Instead, the output voltage has some finite value which represents an error in differentiation. This phenomenon is commonly known as "drift" and must be carefully controlled if high accuracy is to be obtained using the electronic differentiator circuit.

To analyze the effect of component characteristic variations in various parts of the circuit, drift signals can be inserted into the block diagram representation at suitable points, and the variations in the output caused by these signals can be calculated. It can be shown that the portion of the output signal caused by drift varies in proportion to the rate of change of drift voltages in the main loop amplifier, and to the magnitude of drift voltages in the integrator amplifier. In most applications, the drift rate in the main loop amplifier is not great enough to have an appreciable effect on the output. The error from this source, therefore, is negligible.

Great care must be taken, however, to

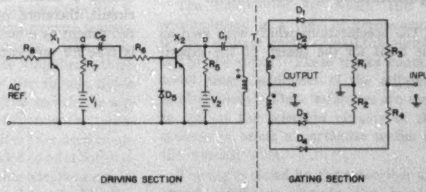

Fig. 8. Schematic diagram of magnetic modulator

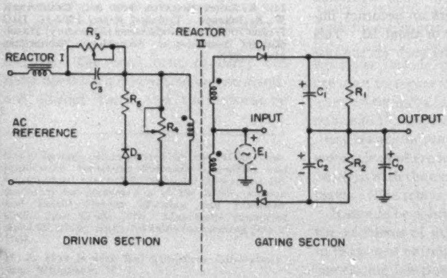

Fig. 6 (left). Schematic diagram of magnetic demodulator

Table I. Summary of Test Results

Design Specifications	Results of Tests on Experimental Unit*
I. The input signal typically has the form of a step followed by a ramp. It is desired to dissipate the transient caused by the step as quickly as possible so that accurate differentiation of the ramp signal can be obtained	
A. Ramp Signal	
1. The ratio between the maximum and minimum detectable rates of change of signal magnitude must be 500 to 1 or greater	Rates of from ±0.004 volt to ±2 volts per second are detectable
2. The accuracy of the differentiation must be within ±0.1% of the maximum rate	The maximum error in differentiation is less than ±0.002 volt which is equivalent to ±0.1% of the maximum rate
3. The maximum detectable signal which must be handled is best defined in terms of the maximum rate of change of signal magnitude. The maximum signal capability must be such that the maximum rate of change can be maintained without saturation for a period of 30 seconds	The unit will handle signals in the range between +30 volts and −30 volts. The total range, therefore, is 60 volts (2 volts per second × 30 seconds = 60 volts)
4. For ramp inputs which do not saturate the system, the maximum period during which differentiation is required is 2 minutes	The unit maintains the specified accuracy at least 2 minutes
B. Step Signal	
1. The maximum step signal which must be handled has the same magnitude as the signal described under A-3	The maximum step which can be handled is from ±30 volts to ∓30 volts
2. The settling time must be less than 4 seconds. Settling time is defined as the length of time following a step during which the accuracy of differentiation is outside the specified limit	For a maximum step input, the settling time is slightly less than 4 seconds
II. The differentiator must operate in an a-c computing system using a 400-cycle-per-second carrier frequency	

* The voltages given are peak rather than rms values.

insure that the integrator drift voltages are reduced to a level commensurate with the accuracy requirements. As mentioned in the section on the integrator circuit, the chopper-stabilization technique is usually used to control the drift characteristics of the integrator amplifier. The effectiveness of this technique depends upon the fact that the mechanical chopper, which is ordinarily used as the modulator, does not itself produce any drift signals. The magnetic modulator circuit described in this paper does produce drift signals. It has been found, however, that by using reasonable care in the design and construction of the circuit, these signals can be made small enough so that the modulator can be used instead of a chopper in many applications involving the electronic differentiator circuit.

Specifications and Conclusions

The specifications which were used as the basis for the design of the experimental differentiator unit are listed in Table I. These specifications themselves are based on conditions representative of those actually encountered in fire-control computer applications. The specified input signals admittedly are idealizations of the actual field signals. Their use, nonetheless, provides a good indication of the differentiator performance, and they are easily simulated in the laboratory.

A summary of the results of the tests which were made on the unit, confirming its conformance with the specified requirements, is also shown in Table I. In meeting the prescribed specifications, the electronic unit has exhibited a marked improvement in performance over that which has so far been obtained using servo differentiators. For a servo which meets the dynamic performance requirements, the best accuracy which the author knows to have been so far obtained is about ±1%. The electronic circuit, therefore, offers an accuracy improvement by a factor of about 10. This is true for applications such as the one described where the computing time is comparatively short. In applications involving long computing times (very low frequencies), servo differentiators remain the best approach to the problem. In the many a-c computing applications where the computing time is comparatively short, the increased accuracy obtainable with the electronic differentiator circuit should recommend its use in spite of the added complexity.

A Magnetic-Drum Storage System Considered for Use as a Common Sender in Nation-Wide Dialing

H. F. MAY
MEMBER AIEE

THE inauguration of direct-distance dialing by the customer requires use of telephone numbers consisting of ten digits. Thus a telephone subscriber in San Francisco will dial 212 CH 3-1000 in order to reach the Bell Telephone Laboratories in New York City. The first three digits are the code for the metropolitan New York area, while the remaining seven digits comprise the telephone number dialed by subscribers within the metropolitan area. To handle calls involving ten digits, the digit-storing capacity of many existing offices will have to be extended and various methods of accomplishing this are under consideration.

The current state of the computer art suggested the investigation of electronic techniques as adjuncts to telephone switching, and a laboratory project was initiated to devise an electronic solution to the problem of extending the digit-storing capacity of no. *1* crossbar and panel sender offices. For economic reasons, a relay solution was eventually chosen for use in the field.

The master drum sender, or MDS, is an auxiliary common (control) register utilizing a magnetic-drum memory to provide 11-digit registering capacity for 156 senders. It provides the circuitry for counting and registering the dial pulses occurring simultaneously in 156 senders and also for outpulsing these digits in multifrequency code after complete numbers have been stored.

Through the use of electronic switching techniques employing transistors and vacuum tubes, the speed is such that a single MDS may be time-shared by 156 senders. The equipment to carry out these operations is mounted on two standard 11-foot racks and the laboratory model of this equipment is shown in Figs. 1 and 2. The motor-driven unit in the background is the magnetic drum. The far bay contains the vacuum-tube read and write amplifiers associated with the magnetic drum and the transistor circuitry which carried out the logical operations required of the MDS. The near bay contains relay equipment used to establish connections with the 156 senders and to apply the multifrequency tones to the selected sender. The actual senders are part of a no. *1* crossbar laboratory system located in an adjacent room. As the model now stands, it contains approximately 500 transistors, 2,000 diodes, 69 electron tubes, and 68 relays.

To convey some idea of the equipment used, the following illustrations are included. Fig. 3 is the magnetic drum used in the laboratory model. It is a drum similar to that used in the DIAD (Drum Information Assembler and Dispatcher) system, another electronic switching system[1] developed by the Bell Telephone Laboratories. The magnetic drum intended for field use is shown in Fig. 4, and this unit is designed for rack mounting. The vacuum-tube circuitry which consists of read and write amplifiers and a clock-pulse generator is shown in Fig. 5. The clock-pulse rate is 60 kc and the clock-pulse width is 2.5 μsec (microseconds). The transistor and diode circuitry are mounted on plug-in printed circuit cards and a typical section of this circuitry is shown in Fig. 6. Detailed views of typical cards are shown in Fig. 7. Both junction- and point-contact transistor are used in this circuitry. The package types include pulse amplifiers which are used to regenerate the signals, diode AND and OR gates used to switch the signals and flip-flops used for memory. Auxiliary transistor amplifiers are used to operate relays where needed to establish connections with the existing telephone equipment. The relays are shown in Fig. 8.

It should be pointed out here that one of the problems of utilizing electronic logic in telephone switching is the difficulty of associating low-power high-speed transistor circuitry with high-power low-speed relay circuitry. To accomplish this requires considerable quantities of intermediate relay storage which poses an economic stumbling block to introducing electronic switching into existing relay offices.

Since some of the equipment utilized in MDS has been discussed, the organization of the system is now explained by reference to Fig. 9, which is a block diagram of MDS. In this diagram, the originating subscriber in a no. 1 crossbar office is shown connected to one of three senders by means of the usual X-bar switching equipment. It is through the originating sender that the MDS picks up dial pulses and sends out multifrequency tones, representing the called number, to the terminating office, which in this case is designated as a no. 5 crossbar office. In the sender there is a relay which follows dial pulses, and the contact of this relay is connected into an electronic scanner. The scanner examines the contact of the pulsing relay in each of the 156 senders every 10 milliseconds. During this short interval, a dial pulse cannot be completed so that the scanner will detect every operation of the pulsing relay. The results of this scanning operation are interpreted by the sender space control as off-normal, preliminary pulse, dial pulse, end of pulse train, etc., and the interpretation is stored on the magnetic drum in a space assigned to each sender. This space is physically 1 inch by 1/4 inch, Fig. 10, and contains 84-unit magnetizable areas known as cells. Within each cell a single bit or pulse can be stored. The drum circuit controls the reading and writing operations on the drum.

The operation of the scanner is synchronized with the rotation of the drum by means of the address circuit so that when a sender pulsing relay is being scanned, the corresponding sender space on the magnetic drum is passing under the reading and writing heads.

The mechanism by which this is accomplished is a pair of permanently written address tracks around the periphery of the drum. These tracks contain serial binary addresses of the adjacent sender spaces. These addresses are used to set up the selection circuits of the scanner to select a particular sender in the crossbar office.

The digits dialed by the subscriber are stored simultaneously in the regular crossbar sender and in the corresponding sender space on the drum.

When sufficient information has been stored in any sender space, e.g., seven

digits, to require action by MDS, the transmitter control swings into action. The transmitter control is continuously monitoring the sender spaces, and it is the function of the transmitter control to take information out of the sender spaces and to control multifrequency outpulsing to the crossbar senders.

All actions are performed by MDS through the senders in the crossbar office. Consequently, the signal level and time scale of the MDS control are dictated by the relay requirements of the crossbar office. The decision-making and memory elements of MDS are electronic in nature and function at speeds measured in microseconds, while the relay operations take place in milliseconds. Because of this thousandfold ratio in speed, the transmitter control carries out its decisions through intermediary units known as transmitters. These transmitters contain both relays and electronic equipment. They receive information at electronic speeds and execute operations at relay speeds through the senders of the crossbar office. Conversely, the transmitters receive information from the senders at relay speeds and then transmit this information at electronic speeds to the transmitter control. Essentially the transmitters are intermediate storage devices for conversion between electronic and relay speeds and signal levels.

The number of transmitters provided in an MDS unit would be determined by the traffic in the central office. It has been

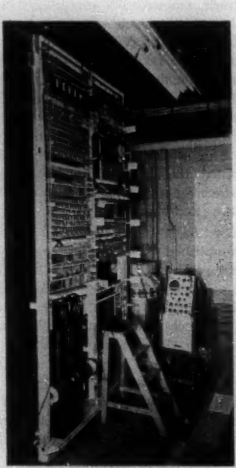

Fig. 2. MDS model, rear view

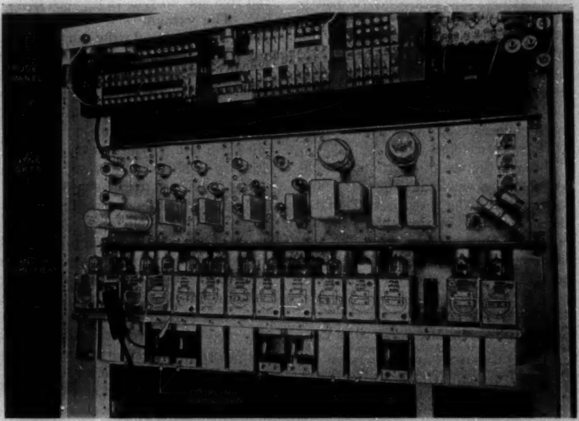

Fig. 5. Drum amplifiers and clock generator

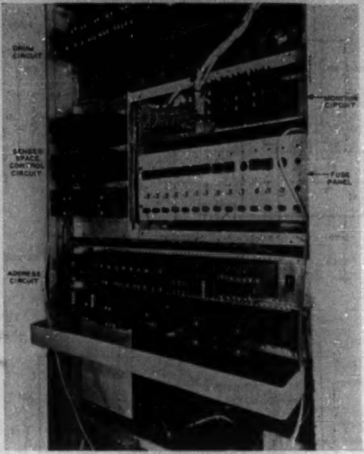

Fig. 6 (left). Transistor and diode plug-in circuitry

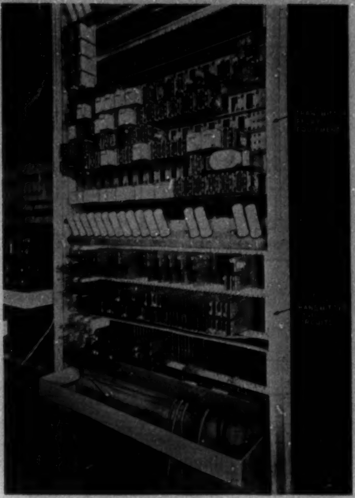

Fig. 8 (right). Transmitter bay

estimated that six transmitters could serve a group of 156 senders in a typical office. In the model, a single transmitter suffices for testing. Where a group of transmitters is controlled by the transmitter control, the first idle transmitter receives the order from the transmitter control. Successive orders for the same sender may be executed by any idle transmitter.

It would now seem appropriate to describe in detail several of the components and their circuits. The magnetic drum is a nickel-cobalt-plated steel cylinder, rotating at 1,500 rpm. Tracks on the surface of the drum are spaced 1/16 inch apart, and the lamination pileup of the head is 0.050 inch wide. Packing factor is about 60 per inch. Pulses are recorded on a saturated background. A unique feature of this magnetic recording system is that single-pass reading and writing is employed. With single-pass operation a cell can be read, the information therein combined in gating circuits with information from other tracks or outside sources, and new information written in the same cell, all while the cell is passing under the head. The reason why this can be accomplished is indicated in Fig. 11. The voltage read back from a recorded pulse is considerably wider than the current pulse which did the recording. This may be caused by leakage flux around the head gap during recording, or by the spread of flux beyond the magnetized area due to the permeability of the magnetic surface. The result is that it is possible to obtain a useful signal from a reading amplifier 2.5 μsec before the write pulse occurs. As a consequence of single-pass operation, the information in every cell in a track can be processed in a single revolution of the drum, and this results in high traffic-handling capacity with a minimum of equipment.

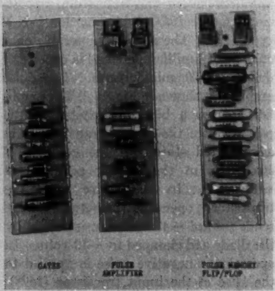

Fig. 7. Typical plug-in cards

To achieve single-pass operation, the reading amplifiers must have a wide passband and a short recovery time after overload. The reading amplifier shown in a previous picture is a plug-in package containing three no. *396A* electron tubes. The circuit is shown in Fig. 12. The first two tubes comprise a linear amplifier with a stabilized gain of 750. The third tube is a threshold stage biased beyond cut-off and a phase inverter. The linear amplifier raises the head voltage (50 millivolts P-P) to 40 volts which is applied to the threshold stage. This stage rejects background noise but responds to the positive-going half-cycles from the linear amplifier. The phase inverter provides a complementary output so that signals are available for both "zero" and "one."

The writing amplifier is similar in external appearance to the reading amplifier and also utilizes three *396A* electron tubes. This circuit is shown in Fig. 13. Two of the tubes operate as blocking oscillators, one serving to generate a "write 1" pulse and the other generating the "write 0" or erase pulse. The oscillators produce a 0.25-ampere current pulse in the head when triggered from the buffer amplifier which is the input stage.

The reading and writing amplifiers are coupled to the magnetic head through a transient suppressing network. This network damps the trailing edge of the writing pulse so that any tendency to ring is damped out before the next cell is reached. By keeping down the amount of reactance in the coupling circuits in the read amplifier, its recovery time is short enough so that it is ready to read within 7 μsec after the write pulse.

The major portion of the MDS circuitry consists of germanium diodes

and transistors which together with associated resistors are mounted on plugin-cards such as shown in Fig. 7. These cards are produced by conventional etched circuit techniques. Diode AND and OR gates are used to carry out the logical operations in a manner usually employed in computers. Yokelson and Ulrich[2] describe the details of design of these gates.[3] However, to complete the description, the several types of gates used in MDS are shown in Fig. 14. AND gates consist of a load resistor fed from negative battery, and one diode for each input. These inputs are at potentials of either −15 (zero) or −30 (one), and the most positive input determines the output. All inputs must be at −30 (one) for the output to present a "one" signal.

OR gates consist of a load resistor fed from ground and a diode for each input. Potentials applied to the inputs are the same as for AND gates but the reversed polarity of the diodes now allows the most negative input to determine the output. Thus a single −30-volt (one) potential produces a "one" output.

A rather special form of gate which can provide high-current output pulses at a low duty factor is the transmission-type AND gate. This gate is used to couple a low-power flip-flop to pulse amplifiers. In this unit, the condenser *C* is discharged to a −30-volt potential by the clock pulse. If a −30-volt potential is maintained between clock pulses by the flip-flop output, the condenser charge remains unchanged and the next clock pulse produces no change in charge. If the flip-flop output rises to −15 volts between clock pulses, the condenser will charge to this potential through high resistance R_s. The next clock pulse will discharge the condenser and produce an output current pulse. The transmission gate integrates a relatively small current over a time interval of about 7 μsec and delivers a pulse of 2-μsec duration and correspondingly higher current.

Pulse amplifiers are used to regenerate the various signals in MDS. These amplifiers utilize two transistors, a point-contact type *1698* and a junction P-N-P type *1778*. The amplifier operates on a current of 1 milliampere and is capable of delivering 80 milliamperes. The pulse amplifier is shown in Fig. 15. The amplifier acts as a bistable switch. In the passive state the output transistor is in a saturated state and the collector is essentially at the emitter potential of −12 volts. In the active state the transistor is open and the output voltage tends toward −48 volts but is caught by the diode and clamped to −30 volts. In operation a negative pulse is applied to the base of the input transistor (*1698*). Conduction from emitter to base turns the transistor on and because of the

trigger characteristics of the point-contact transistor, it remains in a conducting state until turned off. When the trigger stage is on, the output stage is turned off. The trigger stage remains on until the emitter potential is reduced below the base potential of −7 volts. The emitter is supplied from a clock-pulse amplifier called an "enabler." For the duration of the clock pulse, the emitter of the point-contact transistor is connected to −4 volt. At the end of the clock pulse the emitter is supplied from −12 volts through 5,100 ohms. This drops the emitter below the base potential and turns off the transistor. When the point-contact transistor turns off, the output transistor turns on and output voltage rises to −12 volts.

Another basic circuit used in MDS is the flip-flop which is used as a memory element. These are bistable symmetrical circuits utilizing two N-P-N transistors, type *1858*. The circuit of a flip-flop is shown in Fig. 16. The flip-flop operates on a 5-volt negative pulse and its output signal levels are approximately −17 and −36 volts. Since the flip-flop can supply very little current it is always used with a transmission-type AND gate as previously described.

As a simple example of the type of circuitry in which these component packages are used, consider the logical operations employed in adding a pulse to a binary number stored in the drum. This will explain the advantages of single-pass reading and writing. It is first necessary to understand the clock-pulse timing and this is shown in Fig. 17. The important thing to note is the existence of three separate clock pulses during each cell space or cycle. The read-synchronizer or *RS* pulse precedes the write-synchronizer *WS*, and the enable pulse *ES* includes both *RS* and *WS* within its envelope. All signals read from the drum are gated by *RS*. All writing is gated by *WS*. The signals read from the drum and gated by *RS* are used to operate pulse amplifiers which lock and remain active until the enable pulse ceases. These basic operations are shown in Fig. 18.

Assume now that on the drum in a particular row of three cells the binary number *011* is stored and it is desired to add one pulse to this number. It is necessary to change the recorded number to *100* which requires two carries. The logic to do this is shown in Fig. 19. The headings 2^0 etc., indicate the binary columns and tracks on the drum, one of which was detailed in Fig. 18. Each binary column has two pulse amplifiers one of which is active during the enabling-synchronizer pulse. Which one is active depends upon whether a "zero" or a "one" is written on the drum in this column. It must be realized that additional gates are provided to generate the "add one" pulse at the instant that the binary number *011* is being read. When the "add one" pulse arrives at the pair of AND gates in column 2^0, it finds gate *A1* primed by the "read one" signal from the drum. When *WS* occurs, the gate opens and a pulse is sent to the write amplifier to write a zero in this column. This erases the "one" first read. The pulse from gate *A1* also is fed into the AND gates in column 2^1. Here again it finds gate, *A2* primed by both the output of the pulse amplifier and *WS* so that the pulse opens gate *A2* which triggers the write amplifier to write a "zero" in column 2^1. The same pulse is fed to the AND gates in column 2^2 where it finds gate *A3* primed. The pulse opens gate *A3* which triggers the write amplifier to write a "one" in column 2^2.

The entire action of reading and changing the content of a group of cells has occurred during a single passage of the group of cells under the heads. It will be seen that this technique makes it possible for MDS to service an entire group of senders during each revolution of the drum without intermediate storage. Not only is the need for intermediate storage eliminated, but the speed of operation is increased so that a single unit of MDS can serve 156 senders.

The operation of the MDS in the laboratory brought out a number of problems which had to be solved. First the transients developed in relay circuits many feet from the MDS rack produced false signals in the low-level electronic circuits. To reduce this interference required a more liberal use and a more careful design of suppressor than is customarily used for contact protection. Power leads entering the MDS rack had to be filtered to prevent transients from entering on these leads. Another problem not completely solved is how to fuse transistor circuits. Ordinary fuses are too slow in blowing to protect transistors. Experience in the laboratory indicates the need for better trouble-shooting techniques. It is no longer possible to use the very convenient relay techniques of visual observation and "toothpicking." Every observation of microsecond pulses requires carefully chosen test points, and, what is more important, some means of knowing when to observe. For this reason a synchronous system such as MDS has advantages over an asynchronous system. Much work remains to be done in the field of automatic trouble analysis on electronic switching systems.

In conclusion, experience with the MDS indicated that a relay solution to the problem of storing additional digits in existing central offices would prove more economical than the MDS. The knowledge gained from this project has been of value in the design of a complete electronic switching system now in progress.

Matrix Analysis of Logical Networks

E. J. SCHUBERT
ASSOCIATE MEMBER AIEE

Synopsis: A novel method of matrix algebra is derived for the analysis of networks representing logical systems too complex for conventional approaches using Boolean algebra. It is shown that truth tables of system blocks may be treated as matrices and that logical operations on such matrices can be performed efficiently.

THE ANALYSIS of logical networks employing the techniques of Boolean algebra becomes impracticable when the logical function is dependent on many variables. In order to analyze logical networks, several simple computers[1–4] have been designed. With the matrix concept outlined, up to ten variables have herein been mathematically analyzed without the aid of a computer in a time shorter than that required to set up a computer program for the same problem.

Logical Networks

Any network performing logical operations may be represented by a set of voltage sources and sets of circuit elements. Voltage and impedance are understood to be limited to two states only to express ONE and ZERO conditions. The total current I follows the general equation (see Fig. 1)

$$I = U_1Y_1 + U_2Y_2 + U_3Y_3 + U_4Y_4 \qquad (1)$$

wherein the admittances of the branches might be functions of the independent logical variables as follows:

$$Y_1 = Y_1(X_1, X_2, X_3, X_4) \qquad (2)$$

The products in equation 1 involve logical AND operations between the variable voltages U_1 and the correlated branch admittances Y_1. Summing these AND terms implies the OR condition.[5]

The behavior of this types of network can be explicitly described in a truth table by referring to any possible combination of the p independent variables. The set of p variables may assume 2^p states either in an AND or an OR condition, called "minterm" and "maxterm," respectively. A minterm N/maxterm M is any one of the 2^p distinct AND/OR conditions of all p variables in which these variables are or are not complemented in any of the 2^p possible ways.[6] The suffix of N or M is the decimal equivalent of the binary number formed by writing ZERO for each complemented variable and ONE for each uncomplemented variable, in the order of their appearance.

No further discrimination between voltage and impedance as logical variables is necessary; therefore all independent variables are denoted by X_i in opposition to Y and Z, for logical functions or dependent logical variables, as shown in the diagram and related truth table of Fig. 2. The state of variables X_i is defined by the minterms N; sums of certain

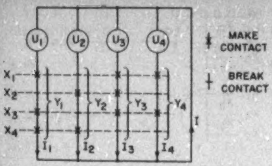

Fig. 1. Contact network performing logical operations

minterms form functions Y. In general any function Y of p variables can be expressed as a polynomial of all minterms with appropriate coefficients F_q.

$$Y=F_0N_0+F_1N_1+\ldots+F_qN_q \quad q=2^p-1 \tag{3}$$

wherein the coefficients F_i have the values ONE or ZERO according to the appropriate column for the function Y in the composite truth table.

In the matrix operations described in the following the conventional matrix notation is supported by index notation as a supplement. Using the Einstein convention, i denotes the dummy index between $q=0$ and $q=2^p-1$, z is the fixed index. Capital letters designate the individual terms of the corresponding matrices in index notation.[7]

$$Y_z=F_{zi}N_i \tag{4A}$$

Multiplication between matrices implies the appropriate transposed matrix, which is indicated by a suffix t only when needed to avoid ambiguity.

In conventional matrix notation all dependent variables of a network are described by

$$\mathbf{y}=\mathbf{fn} \tag{4B}$$

if the matrices are defined as

$$\text{minterm matrix } \mathbf{n}=(N_0N_1N_2\ldots N_q) \tag{5}$$

$$\text{function matrix } \mathbf{f}=(F_0F_1F_2\ldots F_q) \tag{6}$$

OR Operation

The sum of minterms is by definition an OR operation. Because functions Y are expressed as sums of minterms, any sum of functions Y again will be a sum of minterms. In matrix notation the addition yields

$$Y_1+Y_2=(F_i+G_i)N_i \tag{7A}$$

or

$$\mathbf{y}_1+\mathbf{y}_2=\mathbf{fn}+\mathbf{gn}=(\mathbf{f}+\mathbf{g})\mathbf{n} \tag{7B}$$

The block diagram of Fig. 3 shows the two logical networks with the function matrices f_1 and f_2. Their outputs y_1 and y_2, are buffered into an OR gate. The equivalent circuit, shown in part B of Fig. 3, symbolizes the required function obtained by matrix algebra.

AND Operation

In Fig. 4(A) two logical networks feed an AND gate. To obtain an output y implies that both the y_1 and y_2 inputs into the gate are ONE. Because the state of the output depends on the coefficients of the function matrices, f and g, y can be ONE only if the coefficients in both matrices with identical suffix are ONE. All other minterms must be inhibited. The following relations apply:

$$\mathbf{y}_1=\mathbf{fn} \qquad \mathbf{y}_2=\mathbf{gn} \tag{8}$$

$$Y=(F_iG_i)N_i \tag{9A}$$

$$\mathbf{y}=\mathbf{y}_1\mathbf{y}_2=(\mathbf{fg})\mathbf{n} \tag{9B}$$

Negation

This operation implies that each F_{zi} term must be substituted by its complement F'_{zi}. According to elementary definitions

$$F_{zi}+F_{zi}'=1 \qquad \ldots\text{NOT} \tag{10A}$$

$$F_{zi}'=1-F_{zi} \tag{10B}$$

$$Y_z'=(1-F_{zi})N_i \tag{10C}$$

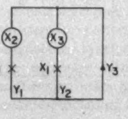
Or in conventional matrix notation

$$\mathbf{y}=(\mathbf{1}-\mathbf{f})\mathbf{n}=\mathbf{f}'\mathbf{n} \tag{10D}$$

As an electrical network is sufficiently described with its impedance tensor, any logical system can be defined by its function matrix. It is understood that the minterm matrix is one-dimensional in any case, comprising only one row or column and identical for any operation performed in a particular system. The function matrix may comprise up to 2^{2p} rows, but in practice only those rows describing utilized outputs are considered.

Function Matrix

In establishing the function matrix, certain rules are pertinent. The columns of the function matrix shall be numbered from 0 at the left up to 2^p-1, corresponding to the dummy index of the minterm matrix. If all variables occur on the inputs of AND gates, the function matrix is directly available as follows.



X_3	X_2	X_1	N	Y_1	Y_2	Y_3
0	0	0	N_0	0	0	0
		1	N_1	0	0	0
	1	0	N_2	0	0	0
	1	1	N_3	1	0	1
1	0	0	N_4	0	0	0
1	0	1	N_5	0	1	1
1	1	0	N_6	0	0	0
1	1	1	N_7	1	1	1

Fig. 2. Logical network and its truth table

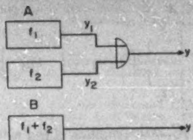


Fig. 3. A—OR condition of two networks. B—Equivalent circuit

RULE I

For the complete set of variables occurring at AND gates, the decimal equivalent of the binary number formed by the state of the variables is the column in which ONE has to be inserted.

$AB'CDE'$ … 10110(b) … 22(d)

In this example an AND gate is set up for all five variables in the system to generate an output for the combination as shown. The number 22 is the decimal equivalent of the binary number corresponding to the state of the inputs for which the gate is operative. Accordingly, in the column numbered with 22 the digit ONE is appropriate.

RULE II

If the set of variables at an AND gate is not complete, the numbers of the columns may be obtained by inserting ZERO and ONE in all possible combinations to form the missing variables, as is indicated by the use of a check mark "√" or any other symbol.

$A\surd C'D\surd$	…	10010(b)	…	18(d)
		10011	…	19
		11010	…	26
		11011	…	27

In columns 18, 19, 26, 27 the digit ONE has to be inserted.

RULE III

A complete set of variables on the input of an OR gate generates a single maxterm, denoted by the suffix similar to minterms. Because the matrix analysis is based on minterms only, a conversion from maxterms into minterms is necessary. As derived by basic Boolean algebra for a particular case:

$$A+B'+C+D+E'=M_{22}=(A'BC'D'E)'=N_9'$$

For the relation of the suffixes of a max-

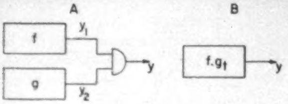

Fig. 4. A—AND condition of two networks. B—Equivalent circuit

term M_i and its equivalent complement of a minterm N_j', the total number p of the variables is the only condition:

$$\text{for } M_i = N_j' \ldots i+j = 2^p - 1 \tag{11}$$

RULE IV

An incomplete set of variables at the input of an OR gate is similar to the situation of Rule II. Insertion of ZERO and ONE instead of missing or irrelevant variables is required to obtain pairs of maxterms, which represent the generated function as follows:

$$M_{i1}M_{i2}M_{i3}M_{i4} = N_{j1}'N_{j2}'N_{j3}'N_{j4}' \tag{12}$$

$$N_j' = \mathbf{f}_j'\mathbf{n}' = \mathbf{f}_j\mathbf{n}$$

$$\mathbf{f}_j = (1-\mathbf{f}_j') = (1-\mathbf{f}_i)^{-1} \tag{13}$$

The complemented minterm is a single term with respect to the complemented minterm matrix, n'. Expressions in minterms involve a function matrix f_j which is directly related to the original suffixes of the maxterms specified in f_i. If the matrix f_i is written in reverse order, the previous coefficient of the column 0 is placed in the last column to the right, proceeding with adjacent coefficients towards the left. This new "reversed" matrix is denoted by the exponent^{-1}. The following rules are obtained immediately:

$$\mathbf{f}_j = (1-\mathbf{f}_i)^{-1} = (1-\mathbf{f}_i^{-1}) \tag{14}$$

$$\mathbf{f} = \mathbf{f}_{j1}\mathbf{f}_{j2}\mathbf{f}_{j3}\mathbf{f}_{j4} = 1-(\mathbf{f}_{j1}'+\mathbf{f}_{j2}'+\mathbf{f}_{j3}'+\mathbf{f}_{j4}') \tag{15}$$

$$\mathbf{f} = 1-(\mathbf{f}_{i1}+\mathbf{f}_{i2}+\mathbf{f}_{i3}+\mathbf{f}_{i4})^{-1} \tag{16}$$

Equations 15 and 16 are applicable to express in function matrices incomplete sets of variables at OR gates.

Network Analysis

A logical system is defined by a set of blocks and the interconnections among these blocks. (Each block is itself a logical network.) Blocks with independent inputs only are designated as first-level blocks. Their outputs can be processed in another group of blocks, which belong to the second level. Eventually other blocks of higher level produce the final output.

The number of levels is pertinent to the classification of a system with regard to complexity, pulse distortion, and attenuation.[8]

One output Y_1 of a first-level block A_1 is defined by

$$Y_1 = \mathbf{y}_1\mathbf{n} = \mathbf{a}_1\mathbf{n} \tag{17A}$$

If this output Y_1 is processed in a block a_k of higher-level k, the output Y_k is obtained.

$$Y_k = \mathbf{y}_k\mathbf{n} = \mathbf{a}_k\mathbf{n} = \mathbf{f}(\mathbf{a}_1, \mathbf{a}_2 \ldots \mathbf{a}_k)\mathbf{n} \tag{17B}$$

All intermediate and final outputs Y_k are described by function matrix operators of the minterm matrix n, that is common to the whole system. It should be emphasized that the dummy indexes are identical with those of corresponding minterms. This reference to the states of the variables is maintained even if the minterm matrices are cancelled in all equations. Hence any matrix arithmetic can be restricted to the function matrices only to determine the relation f of all blocks involved.

$$\mathbf{y}_k = \mathbf{f}(\mathbf{a}_1, \mathbf{a}_2 \ldots \mathbf{a}_k) \tag{18}$$

Conclusions

This paper primarily concerns the introduction of function matrices and operators for the analysis of logical systems. In a subsequent paper, it is planned to expand this concept into a calculus capable of analyzing sequential operations.

It is shown in the appendix that this matrix algebra can be an economical means for analysis of logical networks of higher complexity without the aid of computers.

Appendix. Analysis of a 4-Level System with Eight Variables

In the control of a digital system following requirements expressed in conventional Boolean equations must be met.

$$Y_2 = (X_2+X_3'+X_5'+X_6+X_7+X_8')(X_1X_3'X_4X_6'X_7) \tag{19A}$$

$$Y_4 = X_1'X_2X_3X_4'X_5X_7Y_2' \tag{19B}$$

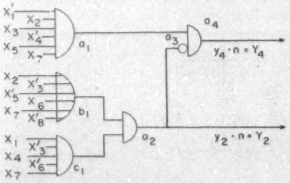

Fig. 5. Routine 4-level design of a network

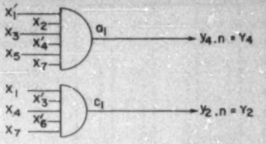

Fig. 6. Reduced 1-level network with identical function

Routine design leads to the network shown in Fig. 5. In view of the number of variables (eight) no attempt would have been made to simplify the circuit using conventional techniques such as the Havard chart.

In matrix notation the same problem is described as

$$\mathbf{y}_2 = \mathbf{b}_1\mathbf{c}_1 \tag{20A}$$

$$\mathbf{y}_4 = \mathbf{y}_2'\mathbf{a}_1 \tag{20B}$$

Or in applying the relation, equation 10,

$$\mathbf{y}_4 = (1-\mathbf{y}_2)\mathbf{a}_1 = (1-\mathbf{b}_1\mathbf{c}_1)\mathbf{a}_1 \tag{20C}$$

AND gate a_1 processes the inputs X_1' X_2 X_3 X_4' X_5 X_7, or in binary notation

01101√1√

Because two variables are missing, 2^2 minterms will be required and are defined by inserting ZERO and ONE in all combinations for the marked bits:

01101010(b)	106(d)
01101011	107
01101110	110
01101111	111

The second column is the decimal notation of the dummy index for the minterms or ONE's occurring in the function matrix a_1, corresponding to equation 21(A).

For the OR gate b_1 the appropriate dummy indexes i of the maxterms B_i are calculated and used to denote the ZERO coefficients of the appropriate minterms B_j in equation 21(B), with the understanding that all other matrix coefficients must be ONE in accordance with equation 16. It should be noted that j is simply the complement of i as shown in equation 11.

i = √10√0110
j = √01√1001

j_1 = 00101001(b)	41(d)
j_2 = 00111001	57
j_3 = 10101001	169
j_4 = 10111001	185

Five variables are present at the AND gate c_1; accordingly 2^3 or eight minterms will be generated as indicated in equation 21(C) and are obtained by the method used before for block a_1.

Because both outputs Y_2 and Y_4 are obtained from AND gates a_2 and a_4, respectively, only the 16 columns identified in the foregoing out of the total 256 columns need to be considered. As a matter of convenience the dummy index is written vertically and applies for all matrices; ZEROS are inserted only where pertinent.

Inspection of the function matrices

$$\text{dummy index}\left\{\begin{matrix}0 & & 0\;0\;0\;0\;0\;0\;1\;1\;1\;1\;1\;1\;2\;2\;2\;2 & & 2\\ 0 & & 4\;5\;7\;7\;8\;9\;0\;0\;1\;1\;6\;8\;0\;0\;1\;1 & & 5\\ 0 & \ldots & 1\;7\;3\;5\;9\;1\;6\;7\;0\;1\;9\;5\;1\;3\;7\;9 & \ldots & 5\end{matrix}\right\}$$

$$\mathbf{a}_1 = (\qquad\qquad 1\;1\;1\;1 \qquad\qquad) \tag{21A}$$

$$\mathbf{b}_1 = (1\ldots 1\;0\;0\;1\;1\;1\;1\;1\;1\;1\;1\;0\;0\;1\;1\;1\;1\;1 \ldots 1) \tag{21B}$$

$$\mathbf{c}_1 = (\qquad 1\;1\;1\;1 \qquad\qquad 1\;1\;1\;1 \qquad) \tag{21C}$$

$$\mathbf{a}_2 = \mathbf{b}_1\mathbf{c}_1 = (\qquad 1\;1\;1\;1 \qquad\qquad 1\;1\;1\;1 \qquad) = y_3 \tag{21D}$$

$$\mathbf{a}_3 = 1 - \mathbf{a}_2 = (1\ldots 1\;1\;0\;0\;0\;0\;1\;1\;1\;1\;1\;1\;0\;0\;0\;0\;1 \ldots 1) \tag{21E}$$

$$\mathbf{a}_4 = \mathbf{a}_1\mathbf{a}_3 = (\qquad\qquad 1\;1\;1\;1 \qquad\qquad) = y_4 \tag{21F}$$

directly reveals that the following conditions exist:

$$\left\|\begin{matrix}y_4\\ y_3\end{matrix}\right\| = \left\|\begin{matrix}a_1\\ c_1\end{matrix}\right\| \tag{22}$$

The blocks b_1, a_2, a_3, and a_4 do not contribute to the outputs in any respect and are redundant.

Fig. 6 indicates the reduced network involving a single level which performs the same function. The analysis eliminates four of six blocks.

The Economics of Component Parts Selection

E. F. FUEGEL
MEMBER AIEE

IT IS OFTEN SAID that the best buy is not necessarily the lowest cost article which can be purchased. It is usually the article which will perform the required function for the required time with minimum over-all cost. Equipment may be designed to meet one or intermediate grades of the following requirements:

1. Lowest manufacturing cost (where maintenance costs are unimportant).
2. Minimum total cost (consisting of manufacturing, installation, and maintenance costs for the required time the equipment is to be used).
3. A minimum number of failures for the required time. (No compromises are to be made in manufacturing, installation, and preventive maintenance to achieve this goal.)

The first requirement involves the selection of parts for which the principal criteria are minimum purchase price and installation cost. Items such as toys are in this category. The economics involved for this requirement are obvious and will not be discussed in this paper. The third requirement, in general, involves customers concerned with the protection or maintenance of human life, where the best available components are selected and economics are trivial.

Most industrial equipment or systems must meet requirement 2 or be intermediate between requirements 2 and 3. By contrast, entertainment and domestic equipment generally is in the range of requirements 1 and 2. Because a good share of the total electronics business falls in this category, a large number of component parts—tubes, transistors, resistors, capacitors, and transformers—are designed specifically for requirements 1 and 2.

When such components are applied to systems that must meet requirements 2 and 3, as in the case of many business machines, the result is often unsatisfactory performance. To design a satisfactory system, i.e., one that meets the necessary levels of reliability, the engineering team must possess numerous abilities, including a thorough knowledge of the requirements, environmental conditions, design technique, and component parts selection and application.

Reliability

Business machines, like many types of electronic equipment, are designed to provide the maximum output for minimum cost over a long period of time. A further requirement is that erroneous output information cannot be tolerated. The equipment should cease to function, or the choice to continue or stop processing information should be under the control of the programmer, or the equipment should be self-correcting, with an indication of what failed when maintenance is required. Where pay checks are involved, for example, the cost of errors can become intolerable.

The reliability of the system must be high. Reliability is defined as the probability that a system, when operated as intended, will provide the desired performance for the desired period of time. If a component part is used in significant quantities, the probability that a certain percentage of these parts will be within certain limits under known operating conditions can be determined, when the rating, parameter limits, environmental conditions, and time are defined.

For purposes of this discussion, the following definitions are assumed:

1. *Component part.* Basic unit, such as tube, transistor, resistor, capacitor.
2. *Component.* Grouping a number of component parts into a circuit, for example, an oscillator, register, or counter.
3. *Equipment.* A number of components, usually housed in a cabinet, making up units like a card punch, sorter, tape storage unit, or memory. An equipment may be a complete entity (card punch, for example) or it may combine with other equipments to form a larger system.

Paper 57-678, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting, Montreal, Que., Canada, June 24–28, 1957. Manuscript submitted August 7, 1956; made available for printing July 9, 1957.

E. F. Fuegel is with the International Business Machines Corporation, Poughkeepsie, N. Y.

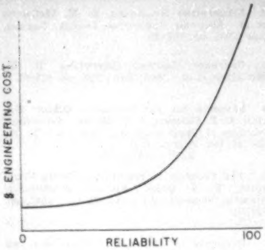

Fig. 1 (left). Diagram showing how engineering costs increase as desired reliability increases

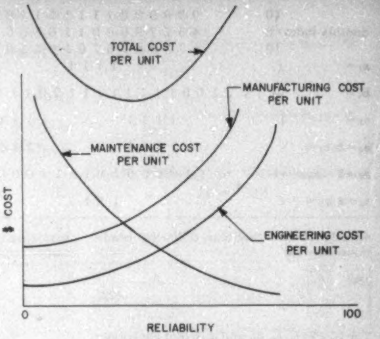
Fig. 3 (right). Illustration of how higher manufacturing costs are sometimes necessary to obtain the desired reliability



4. *System.* A complete operating unit, such as a digital computer, generally made up of a combination of equipments.

Duplicate Systems

The user of a system or equipment might define reliability as "the probability that the system or equipment will do satisfactorily what it is expected to do when I want it done." One way by which the customer can obtain greater reliability is to buy two machines. Then if one does not work, he can use the other one. The odds on completing the job with two machines are better than with a single one. Whether the second machine can be called redundant depends on two factors: the reliability of the first machine, and the reliability that the customer requires. If machine reliability is 95% and the customer is satisfied with 75%, the second machine is redundant. If the best machine available works only 50% of the time, then the customer must have two to meet his requirements. Duplicating entire machines is an extreme measure. The cost is generally prohibitive unless the second machine can be used for supplementary operations that do not have to be performed at specific times.

Duplicate Components

Another possible way to improve reliability is to duplicate unreliable components. This is only possible when the additional circuitry and parts required do not lower the over-all reliability of the system. In general, duplicating selected components rather than entire systems is preferable from a standpoint of cost, size, and weight. The duplication procedure may be expanded to three or more parallel sets of components, as required to obtain the necessary reliability.

The over-all reliability gained by duplicating components may be greater than that obtained from duplicate systems. The use of duplicate systems versus duplicate components may be considered analogous to two chains holding a load; if one link breaks, any link in the second chain must be able to hold the load. If a single chain is made with the same links so that two links are in parallel throughout the length of the chain, the failure of one link will mean that only one single link will be required to hold the load. Intuitively, it can be reasoned that the second chain is more reliable than the pair of chains.

The use of duplicate rather than single components is generally not advantageous from the viewpoints of cost, size, and weight. It should only be resorted to after all the other ways of obtaining the necessary reliability have been thoroughly explored. These include improved manufacturing and quality control methods, better design, better application of component parts, the use of duplicate component parts, and the use of marginal checking.

Marginal Checking

This is a method for detecting progressive degradation before actual equipment failures occur. It can be done as part of a preventive maintenance procedure, to improve system reliability from the customer's point of view. However, this type of checking does not spot potential catastrophic failures. Also, rapid marginal checking of the component parts

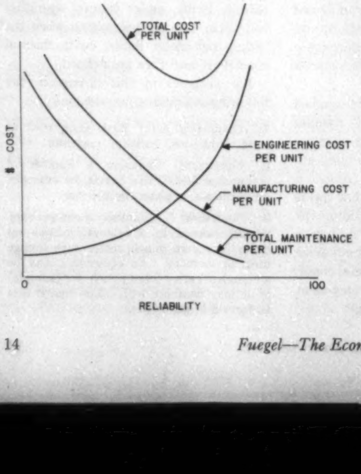


Fig. 2 (left). Curves showing that an increase in engineering effort can improve reliability and decrease manufacturing costs

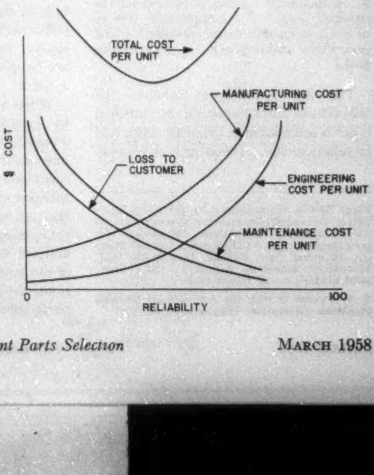
Fig. 4 (right). Diagram including "loss to customer" cost which can affect the total cost curve



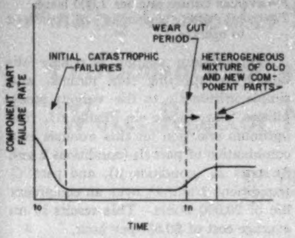


Fig. 5. A typical curve for the failure rate of component parts versus time

in equipment may require additional circuitry that will increase the total size, weight, and cost. The additional cost of such equipment, the cost of maintenance and periodic testing, the reliability obtained, and the availability of the equipment to the maintenance man are factors that must be considered carefully before a marginal checking system is advocated.

Rating of Component Parts

It is well known that many good component parts are available. A large percentage of equipment failures are caused by poor selection, control, and application of component parts. To design reliable equipment, the circuit designer must apply these components in a way that provides the best performance.

Using the manufacturer's rating or arbitrarily altering it to one half or twice the rating will not necessarily provide the desired results. The probable life of a component part depends on how it is applied. The manufacturer's rating is often arbitrary and is usually not the best rating for the equipment which is being designed. Frequently it is possible to select less expensive component parts and obtain the desired reliability by derating.

The tolerance on the purchased component part is the manufacturing tolerance. It in no way indicates how much larger the tolerance will be after the part has been in service for the desired time. It is this larger tolerance that is applicable and it will be referred to here as the design tolerance

The rating and the design tolerances of component parts which can be manufactured within reproducible limits should be based on the period of time during which the equipment is expected to operate. The rating and design tolerance which is determined by life-testing are based on the probability of a certain percentage of component parts remaining within the design tolerance for the required time. The basis for the rating, design tolerance, and survival percentage includes the availability and the cost of the parts.

The life testing of component parts to obtain the probable survival percentages for intermediate times is expensive but necessary. Manufacturers of component parts generally do not have data available for each type of equipment requirement because of the immense variety of requirements and the expense of obtaining the data. Many manufacturers only test their own and competitors' products to determine whether they have improved their product, and to see what their competitive position is.

Table I. Selection and Application of Typical Component Parts

Component Part	Purchase Cost of Part (P)	Labor Cost to Replace (L_o)	Number of Parts (N)	Average Failure Rate per 1,000 Hours (F) for T_n			
				T_n 5,000	T_n 10,000	T_n 20,000	T_n 50,000
A_1	$0.80	$5.00	60	0.01	0.01	0.01	0.01
A_2	1.90	3.00	60	0.005	0.005	0.005	0.005
A_3	3.50	3.00	60	0.001	0.001	0.001	0.001
B_1	0.03	8.50	360	0.0005	0.001	0.002	0.005
B_2	0.15	5.00	360	0.001	0.0006	0.0008	0.001
B_3	0.50	5.00	360	0.0001	0.0001	0.0002	0.0003
C_1	0.25	4.50	250	0.001	0.002	0.003	0.004
C_2	0.75	4.50	250	0.0001	0.0001	0.00015	0.0002
D	Large number of miscellaneous parts; maintenance estimated from experience on previous equipments.						

Conditions:

1. If quantity of part *B* is increased by 20%, failure rates of *A* decrease by 10%.
2. If design tolerance of *B* is reduced by 3%, failure rates increase: B_1 by 25%; B_2, 10%; B_3, 5%. However, quantity of part *A* is reduced 15% and the failure rates remain the same. Also, population of part *C* is reduced 15%.
3. If the voltage rating of part *C* is halved, the cost of all parts *C* is reduced 40%. However, failure rate of *C* increases by a factor of 8.
4. Ten per cent of the part *C* failures will cause an equal number of additional parts *A* to fail.
5. Loss to the customer (L_c) each time a failure occurs is $6.00.

Why Life-Test Component Parts?

The advantages of life-testing component parts are as follows:

1. An estimate of the reliability of a component or system may be determined from the component part reliabilities before even a prototype is built. Changes can be made more readily in the design stage to obtain the desired reliability.
2. A basic group of component parts can be used in a large number of components. A number of samples must be life-tested to obtain reliability data, which in the case of components or systems may be more expensive, especially if a number of changes have to be made to obtain the desired reliability.
3. The time involved in life-testing components or systems is prohibitive when a life expectancy of 20,000 or 50,000 hours is desired. Utilizing standard component parts facilitates reliability and reduces the time and over-all cost. The component parts art does not change as rapidly as the requirements for new circuits. Therefore, estimates of the reliability of parts can be obtained before parts are used in circuits.
4. Improvements and cost reductions in component parts can be recognized and incorporated in existing or new components if a continued surveillance is made on component part reliability.

It is not to be inferred that evaluation of the component or system is not necessary. The component must be evaluated to determine that the component parts are applied properly, including the dependence of component parts on each other, and that the component will function as desired initially, and for the desired life expectancy.

Cost Considerations

Engineering Costs

The cost of engineering a reliable product usually increases as the desired reliability increases. This relationship is shown in Fig. 1. It is usually more expensive to achieve a simple design than a complex one. Designing equipment that will minimize manufacturing errors takes considerably more effort than evolving designs which do not take manufacturing difficulties into account. As reliability is increased, the costs of evaluation, testing, design, and control all increase.

Total Cost

The manufacturing cost may either increase or decrease as a function of reliability, depending on the type of equipment, manufacturing methods, manufacturing difficulties, design complexity, and the selection and control of materials

Table II. Cost of Parts Based on Data from Table I

Component Part	Applicable Conditions	Equipment Life in Hours (T_n) 5,000	10,000	20,000	50,000
A_1	2	$ 72			
A_1	2		$106		
A_2	2, 3			$157	
A_2	2				$213
B_1	2	27			
B_1	2		76		
B_2	2			125	
B_2	2				245
C_1	2	64			
C_1	2		99		
C_2	2, 3			151	
C_2	2				183
D		100	150	300	$1,900
Total cost		$263	$431	$733	$2,541
Cost per hour		$0.053	$0.043	$0.037	$0.051
Average no. of failures excluding (D)		4.9	14.2	17.1	10.6

in the product. It is often possible to improve reliability and reduce manufacturing costs by increasing the engineering expenditure. Such a situation is illustrated in Fig. 2. With some equipment, however, the desired reliability can only be obtained by complex manufacturing procedures and controls, more expensive materials, and complex designs. In such cases the manufacturing cost will increase as reliability increases, as shown in Fig. 3.

The sum of the manufacturing, maintenance, and engineering costs over the desired life is the criterion that determines the optimum allocation of expenditures. Thus, in Figs. 2 and 3 the total cost per unit curve is the most significant one, and the lowest point on it is the ideal operating point, economically speaking. However, in most cases customer demands for high reliability must be considered, and compromise made on the optimum operating point. From the plant controller's point of view, the figures can be used in determining the ratio of income to expenditures.

CUSTOMER LOSSES

Another factor that should be considered in the total cost is the loss to the customer caused by equipment failure (as shown in Fig. 4). If other costs remain the same, the "loss to customer" cost will have the effect of shifting the total cost curve towards higher reliability. The required reliability is that which will provide the maximum profit to the customer. Optimum reliability is usually determined by past experience and good judgment, taking into account the factors previously discussed plus items such as competitive position, time, state of the art, taxes, interest, and market conditions. As more information becomes available by increased use of computers and accounting systems, it will be possible to determine optimum reliability more accurately. It may be possible to use methods involving successive approximations.

Example

Experience with a number of equipments indicates that the failure rate versus time characteristic for large numbers of a component part type generally takes the form shown in Fig. 5, where parts are replaced in the system immediately after a failure occurs. The plateau at the right in Fig. 5 is the result of replacing failed component parts, since these replaced parts generally have a higher probability of surviving to a specified time than those which have been in the system longer. The average failure rate is the portion of the population which fails during a specified time.

Tables I and II illustrate the economical selection and application of parts, using the principles previously described. Table I lists groups of typical component parts, showing numbers used, purchase and replacement costs, and failure rates. (These are average failure rates per 1,000 hours for periods of 5,000, 10,000, 20,000, and 50,000 hours. They depend on how the component parts are applied in the circuits, and on the environmental conditions. E. E. Brewer[1] has discussed various methods of obtaining operating failure rates from component part failure rate data.) Also shown in this table are five assumed conditions that will govern the calculations of this example.

Table II shows the costs as worked out from the data of Table I, and indicates the optimum selection of parts *A*, *B*, and *C* under conditions 1, 2, and 3 (conditions 4 and 5 apply to all selections). The cost of a part, neglecting factors like interest, installation cost, and inspection cost, is calculated from the following formula:

$$P(N)+(P+L_a+L_o)(N)(F)(T_n/1,000)$$

where

P = purchase cost of part
N = number of parts
L_a = cost of replacing failed part
L_o = loss to customer when part fails
F = average failure rate per 1,000 hours
T_n = total time equipment is expected to operate

The optimum solution is readily obtained by applying this formula and simple arithmetic to the various possibilities. As shown in Table II, the optimum selection for this example is a combination of part A_2 (conditions 2 and 3), part B_2 (condition 2), and part C_2 (conditions 3 and 2), over an equipment life of 20,000 hours. This results in an average cost of $0.037 per hour.

Conclusions

To make improvements in the reliability evaluations and procedures, it is necessary to have a continuous field survey program that correlates laboratory and design procedures with actual field equipment and component part failures. Also, a constant watch must be kept on the quality control inspection of incoming component parts, to see if the part manufacturer is providing a reproducible product within the specified limits. This is necessary because the probable tolerance limits after a specified period of time depend on the probable limits at time zero and the probable aging characteristics of the parts.

The first step in arriving at the best equipment for a particular requirement is a thorough knowledge of the economics, selection, application, and performance of component parts. Thereafter, reliability may be improved in several ways. Expending more engineering effort may make it possible to use component parts with broader design tolerances. This generally will decrease the purchase cost of the parts and improve the reliability of the equipment. Reducing the number of component parts may increase reliability and at the same time cut manufacturing costs. Higher reliability may be achieved by increasing the number of components parts to allow the use of lower cost parts with broader tolerances. Likewise, the most economical results may be realized by duplicating components or using periodic maintenance marginal testing methods.

Analog Computer Study of the Transient Performance of a Dual-Cycle Boiling-Water-Reactor Nuclear Power Plant

DAVID W. LEIBY
ASSOCIATE MEMBER AIEE

AS THE COMPLEXITY of multiloop systems increases, the prediction of their transient performance with the use of conventional linear analytical methods becomes quite difficult. In those cases in which each loop of the system contains several nonlinearities, the application of analog computer techniques becomes an attractive method in the solution of transient performance problems. This paper presents a résumé of an analog computer study of the transient performance of such a complex nonlinear system as represented by a dual-cycle boiling-water-reactor nuclear power plant.

As the first step in studying the power plant transient performance, the system was broken down into a number of individual closed loops. These were simulated and analyzed on the analog computer; then, the total system was interconnected and over-all system performance obtained. In the simulation of the individual control loops and in their interconnection, various simplifying assumptions were made. These assumptions were necessary both to limit the complexity of the simulation to the available simulation equipment, and also to cover areas in which detailed information was not immediately available on system phenomena and parameters. From the results obtained, predictions may be made concerning the general trends in the performance of the power plant for various system disturbances, and the importance of system parameters and their effects upon system performance. This information is quite useful in the determination of design compromises in which certain areas of performance must be sacrificed for considerations in other areas.

Description of Boiling-Water-Reactor Power Plant

The Dresden nuclear power plant is being designed to operate on the dual-cycle boiling-water-reactor principle, which has been described in detail in previous articles in the literature.[1,2] Basically, a portion of the energy is withdrawn from the reactor in the form of high-pressure steam obtained by direct boiling within the reactor core, and a portion of the output is taken in the form of a lower-pressure steam obtained from a heat exchanger. A simplified block diagram of an early version of the Dresden nuclear power plant is shown in Fig. 1, which gives the main components of the power plant system as well as the interconnections of the various flow paths of water and steam. The primary recirculating loop consists of the reactor vessel with its reactor core, the risers through which the mixture of water and steam goes to the high-pressure steam drum and the steam separators, the primary side of the heat exchanger, and the interconnecting recirculating water lines. The high-pressure steam flows either through the bypass valve directly to the condenser or through the primary steam valve to the high-pressure stage of the turbine. The secondary steam generated in the secondary side of the heat exchanger flows through the secondary steam valve to an intermediate pressure stage of the turbine. The condensate from the turbine passes through the associated feedwater equipment and then returns proportionally through the feedwater pumps to the secondary steam drum and into the recirculating water loop to maintain proper water level within the various components of the system. The multitude of auxiliary equipment and functions such as blow-down, demineralizers, make-up water, etc., have been omitted from the block diagram, since their magnitudes and operations are assumed to have insignificant effects upon the transient performance of the power plant during normal operation.

The valves associated with the high-pressure steam flow, the bypass flow, and the secondary steam flow are interconnected through the mechanical and hydraulic system illustrated in Fig. 2. The error signal between the reactor vessel pressure and the reference pressure operates through a pressure regulator to position the mid-point of the pressure link. The error signal between the turbine speed and the reference speed acts through a speed governor to position the mid-point of the speed link. The secondary admission valve is connected through a hydraulic amplifier to the right-hand end of the speed link, the primary steam admission valve is connected through a hydraulic amplifier to the interconnection between the speed link and the pressure link, and the bypass valve is connected through hydraulic amplifying equipment to the left end of the pressure link. In addition, the left-hand end of the pressure link is restrained by a spring to hold the bypass valve in the closed position.

This unique linkage system provides automatic control of both the turbine speed and the reactor vessel pressure when the power plant is operating into an isolated load. If the load is increased upon the turbine, the speed will tend to droop, causing the speed governor to raise the mid-point of the speed link, thereby opening the secondary steam valve to maintain the proper speed on the turbine. If the reactor vessel pressure tends to increase over the reference value, the pressure regulator will raise the mid-point of the pressure linkage, causing the pressure link to rotate about its left end as a fulcrum and the speed link to rotate about its mid-point, thereby opening the primary steam valve and closing the secondary admission valve. If there should be more primary steam flow available than required to maintain load on the turbine, the secondary admission valve will become seated and any further demand for more high-pressure steam flow will cause the output of the pressure regulator to override the restraining spring, thereby opening the bypass valve to the condenser.

One of the attractive characteristics of a boiling-water reactor is its stable operation at constant power when it is operating under constant pressure.[3,4] When the dual-cycle feature is applied to a boiling reactor it is found that the reactor power level is a function of the subcooling of the water entering the bottom of the core. The term "subcooling" is used to describe the difference in enthalpy between the water entering the bottom of the core and the saturation enthalpy at

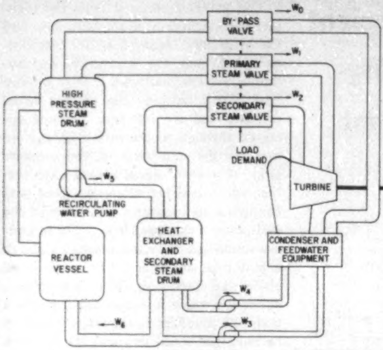

Fig. 1. Dual-cycle boiling-reactor power plant

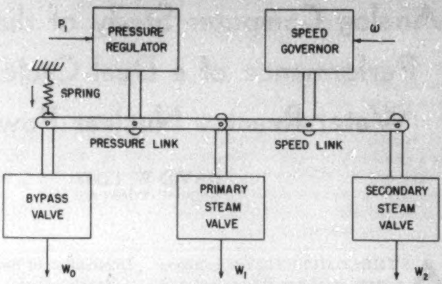

Fig. 2. Steam flow control

the operating pressure. This subcooling of the recirculating water is essentially a measure of the amount of energy being extracted in the secondary steam system plus the energy required to heat the primary steam flow condensate up to the boiling point.

The manner in which the subcooling is related to the total power output of the reactor may be seen by referring to Fig. 3, where three functions within the reactor core are indicated relative to their positions along the axis of the reactor for two different power levels. If the heat flux density from the fuel elements to the coolant steam $Q_\phi(y)$, is assumed to be sinusoidally distributed along the axis of the core, the energy added to the coolant stream, $\int Q(y)$, has the form of a $(1-\cos\theta)$ curve. At some point upward through the core, designated as α, sufficient energy has been added to the coolant stream to bring the recirculating water up to the boiling point. All energy added to the coolant stream from that point upward causes boiling within the reactor core. The difference in the abscissa between the total energy added curve and the subcooling value may be considered as an indication of the bubble concentration. The total area beyond the subcooling boundary line gives an indication of the total steam volume within the reactor core. The steam bubbles within the core cause negative reactivity which must be counterbalanced by positive reactivity from the control rods. For the purpose of this study, the negative reactivity from the steam bubbles is considered to be proportional to the integral of the local bubble population times the relative flux level squared. The reactivity from the bubbles or voids, as a function of distance through the reactor, is given by the $\Delta K_v(y)$ curve with the total reactivity from the voids being represented by the area under this curve.

The two similar diagrams in Fig. 3 are shown for operating at one-half rated power level and for operation at full rated power. In the one-half power condition, shown in Fig. 3(A), the subcooling is equal to approximately 20% of the full rated output of the reactor, causing boiling to begin approximately 40% through the reactor. It may be seen that if the subcooling is increased, the bubble population will diminish, thereby causing an effective decrease in the area representing the reactivity from the voids. Since this reactivity term is negative a decrease in its magnitude puts an effective positive reactivity into the reactor, thereby causing an increase in the reactor power.

When the reactor is operating at full power as shown in Fig.3(B), boiling does not begin until the recirculating water has penetrated over 50% through the reactor. This gives a much shorter region in which the bubbles are present but, due to the increased magnitude of the bubble concentration, the area of the curve which represents the total reactivity of the voids is the same as that in the conditions shown in (A). Since the subcooling of the water entering the bottom of the reactor core Q_s is essentially proportional to the energy being extracted in the secondary steam system, a method of control of the reactor power level over a reasonable power level range is obtained by changing the rate at which energy is withdrawn from the secondary steam system.

Power Plant Simulation

The presentation of all the details of the derivation of system transfer functions and simulations of all components of the power plant is well beyond the scope of this paper. Therefore only the block diagrams of the individual loops within the system will be presented along with a discussion of several of the simulation problems involved in each loop.

REACTOR-VOID FRACTION LOOP

Probably the most important single control loop within the Dresden nuclear power plant is that which expresses the relationship of the reactor power level, the recirculating water subcooling, and the effective reactivity from the steam voids. This loop, which is present within the reactor core, may be represented by a 5-element block diagram as shown in Fig. 4. The reactor kinetics represents the relationship between the reactivity Δk, applied to the nuclear reactor and the output of neutron flux Φ. The fuel element thermal model gives the time-dependent behavior of the heat energy output at the surface of the fuel elements Q_ϕ as a function of the neutron flux level as an input. The void fraction model expresses the relationship between the reactor heat flux and the recirculating water subcooling Q_s, to give an effective steady-state reactivity from the voids Δk_{v0}. The void generation time simulation block considers the time for the growth of the bubbles within the reactor core and the accumulation of the effect of bubbles as a function of the transport time through the core. The fifth block represents the pressure dependency of the effective reactivity in that, as the reactor vessel pressure P_1 increases, a given amount of energy in steam will represent a smaller volume of voids within the

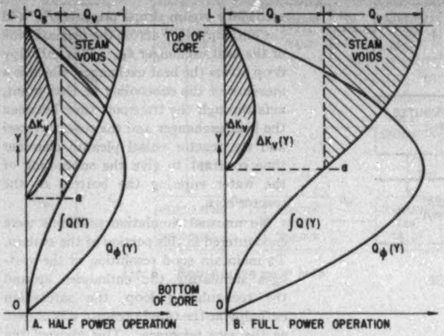

Fig. 3. Reactor void-fraction relationships

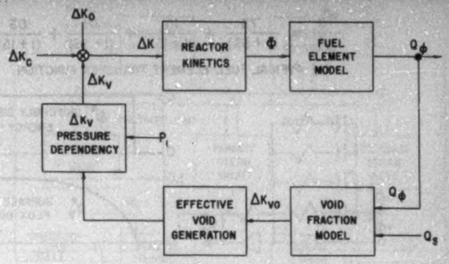

Fig. 4. Reactor void-fraction loop

reactor core. The reactivity from the voids is added with the proper polarity to the reactivity from the control rods, temperature coefficient, Doppler effect, poisons, etc., to give an effective ΔK of zero under steady-state operating conditions. The reactor kinetics is simulated in a conventional manner, which has been described at various places in the literature, by the use of one operational amplifier with the five delayed neutron groups connected across it and one electronic multiplier to obtain the power level dependency of the reactor gain factor.[5,6]

During the early phases of the study of the Dresden nuclear power plant, the fuel element transfer function was considered to be a simple time constant. During the investigation of the stability of the reactor-void fraction loop, a more refined model of the fuel element was found desirable. An expression was derived for the heat transfer to the coolant at the surface of an infinite cylinder having uniform heat generation throughout its interior. Further improvement of the thermal model of the fuel element was made by considering the thermal impedance present in the bond between the fuel material and the jacket of the fuel element.[7] The transfer function for the heat flow across the boundary between the fuel element and the coolant may be expressed as a series of single time constants which may be readily simulated on the analog computer.

The gain constants and time constants in the series expression are functions of the Eigen values of the Bessel functions, the outer radius of the fuel element, the thermal diffusivity of the fuel element material, and the thermal resistance between the fuel element and the jacket. The transfer function of a typical fuel element is shown in Fig. 5, along with its analog computer simulation and the transient response of the fuel element to a step change in uniform heat generation within the fuel element.

The transfer function of the typical fuel element indicates that 75% of the energy occurs through a time constant of 5 seconds, 15% through a time constant of 1 second, and 5% through a time constant of 1/2 second, with the remainder of the energy transfer occurring in smaller and smaller parcels through faster and faster time constants. The response of such a transfer function to a step input then shows up with an infinite slope at the beginning of the transient which decreases as the effect of the faster time constants disappear and the remaining energy comes from the longer time constant contribution.

In the simulation of the void fraction model it was necessary to reproduce the calculated effect of the subcooling of the water entering the bottom of the reactor core Q_s, and the operating level of the reactor Q_ϕ, upon the effective reactivity obtained from the voids. By means of the geometry presented in the void fraction relationships shown in Fig. 3, an analytical expression may be derived for the effective reactivity of the voids as a function of these two system variables, giving the family of curves as shown in Fig. 6. In this figure, each curve represents a given constant power level, the ordinates indicate values of effective reactivity from the voids, and the abscissas represent values of subcooling entering the bottom of the reactor core. This family of curves, or void map as it is often called, is so set up in a per-unit system that for the unit power output curve, unit subcooling causes zero void generation, whereas zero subcooling causes unit effective reactivity from voids. In the power plant configuration under discussion, the operating line is such that full power is obtained at approximately 50% per-unit subcooling. Therefore, the operating line drawn on this family of curves shows that only about 20% of the effective ΔK from voids is present of that which would be present if the reactor were boiling completely at rated power with saturated water entering the bottom of the core. This family of curves shows that with the operating line at the indicated position, control from 100% power down to approximately 25% power is possible by means of variation of the subcooling.

The behavior of the reactor loop may readily be seen by considering operation about some point on the operating line, say at the 0.8 power position, where the subcooling is approximately 37%. If the subcooling were increased to 40%, the operating point would move down along the constant 80% power line which would cause a decrease in the effective reactivity from the voids, thereby causing the reactor power to increase. The reactor power level will then increase to some value of approximately 85% to bring the operating point back to the operating line. In a similar manner, if the subcooling were decreased down to 30% rated value, the operating point would move upward to cause an increase of about 30% in the reactivity from the voids, thereby reducing the reactor power to approximately 70% to bring the operating point back to the operating line.

This family of curves is simulated on the analog computer equipment,[8] as shown in Fig. 7. An electronic divider circuit is operated on by the subcooling Q_s, by the heat flux from the reactor Q_ϕ, and by a

$$\frac{Q^*_\phi}{\Phi^*} = \frac{.75}{(1+5S)} + \frac{.15}{(1+1S)} + \frac{.05}{(1+.5S)} + \frac{.03}{(1+.1S)} + \cdots$$

bias voltage. The output of this divider is a function of the reactivity from the voids. This function is then applied to a function generator which simulates the per-unit power curve of reactivity as a function of subcooling. This function generator uses the forward characteristic of silicon diodes and can reproduce the curve with less than 1.0% error. The simulation of the void fraction map was adjusted to maintain the spacing and the slope of the power curves near the operating line, allowing some deviation at the extremities of the curves. These deviations were not considered serious since normal operation did not cause violent operational departures from the operating line and also because the assumptions made in the calculations of this curve did not warrant the additional effort to obtain a more accurate representation.

RECIRCULATING WATER LOOP

The block diagram of the recirculating water loop, shown in Fig. 8, includes eight components. The thermal model of the reactor vessel takes the primary steam flow W_1, and the difference between the reactor heat rate Q_ϕ and the subcooling Q_s, as the input signals, and produces the pressure in the reactor vessel P_1 as the output signal. The reactor vessel pressure determines the enthalpy h_{60} of the recirculating water leaving the reactor vessel. This enthalpy acts through the time constant of the water storage within the primary steam drum and the transport time between the steam drum and the heat exchanger to give an enthalpy h_{62} at the input to the primary side of the heat exchanger. The steam flow from the secondary side of the heat exchanger W_2 produces the heat exchanger secondary steam drum pressure P_2, and the enthalpy drop across the primary side of the heat exchanger h_{63}. This enthalpy drop across the heat exchanger, which is a measure of the subcooling at that point, acts through the transport time between the heat exchanger and the reactor vessel and the reactor vessel plenum chamber time constant to give the subcooling of the water entering the bottom of the reactor core.

No unusual simulation problems were encountered in this portion of the system. To maintain good resolution of the voltages simulating the enthalpies around the recirculating loop, the saturation enthalpy at the rated pressure was chosen as the zero reference. This allowed the changes in the subcooling to cover the full range of output voltage of the operational amplifier. Each transport time was simulated by an all-pass network utilizing three operational amplifiers.[9] The heat exchanger was simulated by a relatively simple analysis of the single-pass, cross-flow, U-tube type of configuration.[10] A typical response of this portion of the system is given in Fig. 9, in which a step decrease in the secondary steam flow from rated value to zero is applied, such as would occur during a turbine tripout. The secondary steam pressure and the subcooling appearing at the bottom of the reactor are indicated as the output functions. The pressure within the secondary steam drum rises approximately as a single time constant whose magnitude is determined primarily by the weight of water stored within the secondary side of the heat exchanger. The subcooling leaving the heat exchanger follows approximately

the same curve as the secondary steam drum pressure. It appears at the bottom of the reactor core after being operated upon by the transport time between the reactor vessel and the heat exchanger, and the time constant in the reactor vessel plenum.

PRESSURE LOOP AND SPEED LOOP

In the preliminary studies leading up to the total power plant simulation on the analog computer equipment, individual studies were made of the pressure loop and the speed loop. In these studies, the transient performance of the individual loops was investigated for a large number of variations in system parameters and for various driving functions. Since the pressure loop and the speed loop are quite closely interconnected, both through the cross-coupling of their control signals and also by an interconnection of their main integrator elements, it is more convenient to present a block diagram of the combined pressure and speed loops as shown in Fig. 10, rather than the individual block diagrams. The pressure loop under normal operating conditions consists of the pressure regulator, the primary steam valve, and the reactor vessel thermal model. The speed loop consists of the speed governor, the secondary steam valve, and the steam turbine model.

The steam flow control system contains many more individual elements than those shown in the pressure and speed loop interconnection block diagram of Fig. 10. In many places throughout the system, the power requirements are such that several stages of hydraulic amplification devices must be cascaded in order to obtain proper operation of the system. Also, the system includes auxiliary control equipment such as pre-emergency pressure regulators and special hydraulic mechanisms for obtaining particular operating characteristics of the system. To simulate properly the performance of the pressure and speed loops, it is necessary to include the major nonlinearities imposed upon the hydraulic control equipment.

In normal turbine control practice, the oil supply for the hydraulic control equipment is obtained from the same pump that supplies the lubricating oil to the turbine-generator equipment. Therefore the relatively large hydraulic equipment driving the turbine admission valves and the bypass valve mechanisms must not operate at such rates as to demand a greater hydraulic oil flow than that available from the pumps, thereby causing an undesirable pressure drop of the oil system. Since the hydraulic equipment has such physical limits upon the strokes that valves can move no further than fully closed or fully open, it is necessary to insert these limitations upon the simulation of the equipment. Another nonlinearity to include is the effect of the differential areas of the operating pistons of the valve mechanisms, as well as the effect of the static load forces imposed upon the operating pistons.

The analog computer simulation of a typical hydraulic amplifier such as is used in the pressure and speed loop representation is shown in Fig. 11. In Fig. 11(A) a much simplified schematic diagram is given of the hydraulic amplifier, showing its three basic components: the pilot valve, the operating piston, and the feedback linkage mechanism. The two expressions describing the operation of this hydraulic amplifier are given

Fig. 11. Hydraulic-amplifier simulation

in (B), in which the displacement of the pilot valve Y is equal to the displacement of the input X minus the displacement of the feedback from the output position Z, all multiplied by the proper scale factors which are determined by the linkage arm level ratios. The second relationship which holds is that the displacement of the output system is proportional to the integral of the disdisplacement of the pilot valve. This expression is written under the assumption that the rate of flow of hydraulic fluid to the pilot valve is directly proportional to this displacement in either direction of operation.

These two linear operating equations can be simulated by the use of three operational amplifiers as shown in Fig. 11(C). The simulation of the first equation is performed on amplifier 1, the second equation is simulated on amplifier 2, and amplifier 3 is used strictly as a sign changer. The output position of the hydraulic amplifier is obtained as the voltage output of amplifier 2, which has a silicon diode limiter connected across it in order to simulate the stroke limit of the operating piston. The input to this integrator representing the operating piston is so obtained through two adding resistors that for one polarity of input signal, one resistor alone is in the circuit, whereas for the opposite polarity input the two resistors are in parallel. This simulates the effect of the static load upon the operating piston. The output of amplifier 1, which is the position of the pilot valve, is limited in either direction of operation by the two silicon diodes connected across the amplifier. The breakdown voltages of these diodes are selected to obtain the proper rate limits upon the operating piston.

TOTAL POWER PLANT SYSTEM SIMULATION

The over-all simulation of the Dresden nuclear power plant was obtained by the proper interconnection of the various individual control and operating loops. In the final phases of the study, in which several abnormal operating conditions were investigated, up to 70 operational amplifiers, three function generators, and five electronic multiplers were committed to this problem. Since the individual loops and components of the power plant system had been analyzed in considerable detail in the preliminary studies, no great difficulty was experienced in the interconnection of the various loops into the over-all system simulation.

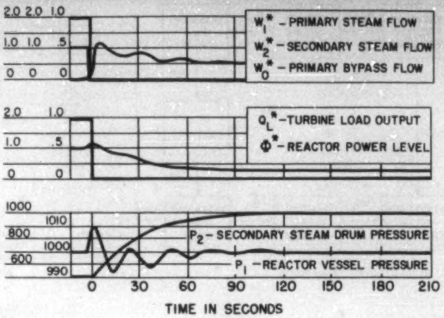

Fig. 12. Transient performance following load tripout

In the scaling of the problem for the computer, a nondimensional form of scaling was used. The electronic multipliers used in this study had scale factors such that 25 volts times 25 volts as inputs gave 25 volts output with a saturation level of approximately 50 volts in the output. Therefore the problem was scaled so that 25 volts represented 100% rated value of the different system variables in those portions of the problem in which electronic multipliers were required. In other portions of the problem 50 volts was chosen for rated conditions. This adoption of a normalized or a per-unit scaling made interpretation of the data quite easy, in that no unusual scale factors were involved. Also, the adoption of this universal scale factor of either 25 or 50 volts for rated conditions eliminated much of the risk of data being recorded at the wrong scale factor.

The immediate results of this study were obtained in the form of recorder charts of the transient performance of different system variables. Throughout most of the study, ten channels of information were recorded. This was obtained by using an 8-channel recorder with a Triplexer connected to the one channel. Since the problem was scaled for real time, the chart speed was sufficiently slow that the Triplexer gave a reasonably good indication of the transient conditions. The nine system variables which were recorded for most of the transient runs were the primary steam flow W_1, the secondary steam flow W_2, the primary bypass steam flow W_0, the turbine load demand Q_D, the actual turbine load obtained Q_L, the nuclear reactor power level Φ, the recirculating water subcooling Q_s, the reactor vessel pressure P_1, and the secondary steam drum pressure P_2. Additional variables recorded were the turbine speed ω, pressure regulator reference P_{1R}, control rod reactivity ΔK_c, accident reactivity ΔK_A, individual bypass valve steam flow W_{0R}, feedwater flow W_s, and other system variables. Several hundred transient responses were taken of the power plant performance for a large variety of driving functions. To maintain control of the accuracy of the data being obtained, a series of log sheets was set up in which each of the transient runs was given an identifying number, with the log sheet reporting such information as the driving function, the variations in the different system parameters being considered, the recorder calibration for all of the channels of information being recorded, and the pertinent information being obtained from the recorder chart. From this relatively large amount of data taken, the observed data were presented as families of curves of system performance indications such as transient pressure overshoot or time to reach certain magnitudes as functions of the various driving functions and system parameter combinations.

Indicated Transient Performance

POWER PLANT TRIPOUT FROM FULL LOAD

One of the most demanding driving functions which can be imposed upon the the power plant, under what are considered normal operating conditions, is the driving function of a power plant tripout from full load. This tripout of the power plant may be initiated either by a loss of load on the generating equipment, or by the tripping of the turbine valves by safety equipment associated with the turbine system. The primary consideration upon tripout is the protection of the turbine equipment from overspeed and also the maintaining of proper operation, where possible, of the prime power source. The response of the power plant to a turbine tripout is shown in Fig. 12. At the instant the tripout occurs, the secondary

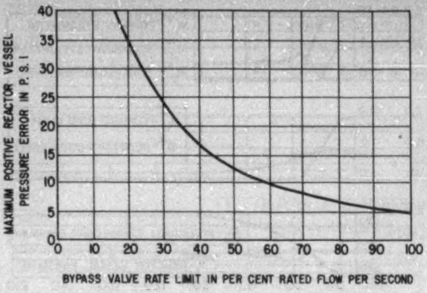

Fig. 13. Effect of bypass valve rate upon pressure transients

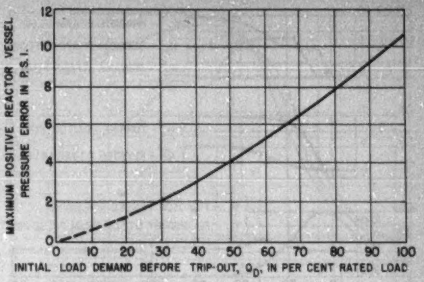

Fig. 14. Effect of tripout level upon reactor-vessel pressure transient

steam flow and primary turbine steam flow decrease to zero very rapidly. With the time constants of typical control system, these valves shut off in much less than one second's time. The primary bypass steam flow then increases up to a magnitude to maintain pressure within the reactor vessel. The rate of increase of this steam flow is determined by the rate limit upon the opening of the bypass valve and is so set that there is no detrimental pressure drop in the oil supply system. The turbine load output drops very rapidly to zero following the decrease in the two steam flows. The reactor power level takes a momentary positive overshoot and then decreases to approximately 20% power in the steady-state conditions which represent the stand-by boiling of the reactor with the control rods at the normal conditions. The primary steam drum pressure overshoots approximately 10 psi (pounds per square inch) and then goes through a damped oscillation until the nominal 1,000-psi pressure is obtained. The secondary steam drum pressure starts out at the 500-psi value of full-load conditions and then increases to the 1,000 psi, which gives the same pressure in the secondary steam drum as in the primary system.

The magnitude of the first oscillation of the pressure loop is determined primarily by the magnitude of the steam flow error signal imposed upon it. This steam error signal is measured by the rate at which the bypass valve opens following the tripout of the primary steam valve. From a series of transients in which this rate limited was varied, the curve of positive transient pressure overshoot of the reactor vessel pressure as a function of bypass opening rate is plotted as shown in Fig. 13. This figure shows that a bypass valve rate limit below approximately 20% flow change per second causes an undesirable positive reactor vessel pressure overshoot of over 35 psi. If the valve is speeded up to the magnitude that the limit is effectively removed and its speed is only limited by its inherent time constant, the positive reactor vessel pressure overshoot is held to a value less than 5 psi.

With the bypass valve rate limit set at approximately 60% flow change per second, and the initial power level as a variable, the curve of maximum positive pressure overshoot as a function of the initial load demand preceding the tripout is obtained as shown in Fig. 14. This shows that the pressure error is practically a linear function of the initial power level before the tripout has occurred.

NORMAL POWER CHANGE MANEUVERS

Two recorder chart representations are now presented which illustrate the normal maneuvers of the power plant in changing power level at a reasonable rate. In the first case, illustrated in Fig. 15, the turbine load demand is increased linearly from zero at the steady-state standby condition to 100% in 25 seconds. At this standby condition, the primary steam valve and secondary steam valve are closed; the bypass valve is allowing approximately 40% rated primary steam flow directly to the condenser; the turbine load output is at zero; the reactor power level is at approximately 20% rated power; the reactor vessel pressure is at the rated 1,000 psi; and the secondary steam drum pressure is also at 1,000 psi.

As the load demand is applied to the turbine control system, the primary steam valve opens to admit primary steam to the turbine simultaneously as the bypass valve closes. At the time that the primary steam valve is carrying all of the the primary steam flow, the secondary steam valve begins to open. The secondary steam valve opens at a rate determined by the power demand, and in this particular case reaches its full open limit of approximately 130%. When the secondary steam valve reaches its limit, there is still insufficient primary steam flow to maintain the desired load upon the turbine. Therefore it can be seen that, at the point where the secondary steam valve hits its limit, the turbine load output deviates from the demand of the 25-second ramp input and does not reach the desired 100% load until approximately 50 seconds after the demand had been initiated. The secondary steam drum pressure does not start to drop until the secondary steam flow is started. Since the recirculating water subcooling does not begin to increase immediately after the secondary steam drum pressure begins to drop because of the transport time delay, the reactor power level does not begin to increase until some time after the initiation of the driving function. This can also be seen from the curve of primary steam flow which remains at practically a constant value until nearly 25 seconds after the transient was started. It then begins to increase at a rate determined primarily by the secondary steam drum pressure time constant acting through the recirculating water subcooling to give a reactor power level value. The reactor vessel pressure is found to be only slightly disturbed by this transient, having a maximum positive deviation from the nominal value of about 3 psi and a negative deviation of less than 1 psi.

In the second case, illustrated in Fig. 16, the power plant demand is assumed to be changed from 100% to 0% load linearly over a 25-second period. The reduction of turbine load demand causes a decrease in the secondary steam flow. When the

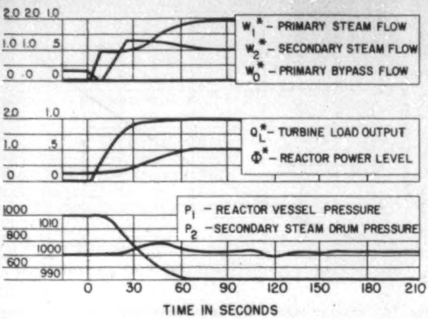

Fig. 15. Transient performance during load increase from no load to full load

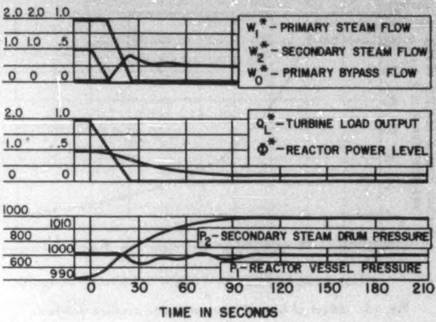

Fig. 16. Transient performance during load decrease from full load to no load

secondary steam valve has been completely closed, the primary steam valve is closed simultaneously with the opening of the bypass valve. In this case, the change in the secondary steam drum pressure begins very shortly after the initiation of the transient, since the secondary steam flow is the first of the two steam flows to change. The recirculating water subcooling begins to decrease, accompanied by a decrease in the reactor power level. It should be noticed that the turbine load output follows exactly the turbine load demand in going from 100% to 0% in 25 seconds of time. The reactor vessel pressure shows a negative error of approximately 4 psi with practically no positive pressure error at any time during the transient. After steady-state conditions are reached, the reactor operates at slightly above 20% rated power with a bypass steam flow of approximately 40% rated high-pressure steam flow.

INDIVIDUAL BYPASS VALVE CHECK-OUT

In the operation of the bypass steam system, the magnitudes of steam flow to be handled are such that one valve is not feasible; rather, a number of valves are operated in sequence. It is estimated that eight valves will be used, each of which will be capable of allowing 15% rated high-pressure steam flow when in the full open position. As one of the operating procedures of the power plant, the operation of each of these individual bypass valves must be checked periodically. Since this will apply a transient to the pressure loop of the system, an indication of the best method of checking of these individual bypass valves is desirable. Each bypass valve is opened at a certain rate, held open for a given period of time, and then closed at one-half the rate at which it was opened. The results of a typical bypass valve flow check is shown in Fig. 17. Under these conditions, the turbine load output remains relatively constant and is not shown on this reproduction of the recorder chart. In this particular case, the power plant is operating at 100% power with rated primary steam flow, rated secondary steam flow, and with no flow through the bypass valve system. The bypass valve is opened in 5 seconds, held open for $2^1/_2$ seconds, and then closed in 10 seconds. The opening of the bypass valve causes a reduction in the reactor vessel pressure which reaches a maximum negative pressure swing of approximately 8 psi. The bypass flow obtained from this check, which first appears as shown in the curve of the bypass flow, causes the pressure regulator to reduce the primary steam flow and thus maintain the reactor vessel pressure. When the primary steam flow drops, the secondary steam flow is increased by the speed governor to maintain load upon the turbine. There is an overshoot of the reactor vessel pressure at approximately this time of the transient, reaching a magnitude of approximately 10 psi over the nominal value. This causes the pressure regulator to open the bypass valve to bring the pressure back to nominal value. There are several cycles of oscillation of the primary steam drum pressure and the three steam flow valves until steady-state conditions are reached. It should also be noticed that there is a slight oscillation in the reactor power level

Since it was desirable to find the best method of checking out the bypass valves with minimum disturbance on the system, a considerable number of runs were taken in which both the rate of opening and the rate of closing the bypass valve were varied, as well as the length of time at which the valve was held open. Data were taken for three values of hold-open time of 0 seconds, $2^1/_2$ seconds, and 5 seconds and for rates of valve opening ranging from 1/2 second for full opening time down to a slow speed of 50 seconds for full opening time. The results of this study are plotted as shown in Fig. 18. In those cases in which the valve is opened quite rapidly, the primary driving function is the area under the curve, which is a measure of the total volume of steam withdrawn. It can be seen that the hold-open time is then quite important in determining the magnitude of the positive pressure error. As the rate of opening of the bypass valve is slowed down, the pressure loop is found able to follow the change in steam flow and to maintain the reactor vessel pressure. As the time of opening approaches 50 seconds, the pressure error is somewhat less than 2 psi. From all considerations, it appears that an opening time of approximately 5 seconds falls in the region of the largest transient disturbance upon the pressure loop of the system.

Conclusions

The basic theory of operation of the dual-cycle boiling-reactor power plant has been pointed out, along with examples of methods of its simulation upon the analog computer equipment, and several specific examples of transient performances as indicated from the simulation. The primary results of the study indicate the general trends of performance to be expected for the system under the assumptions being made in the analysis.

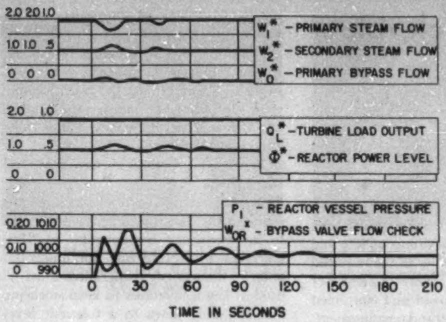

Fig. 17. Transient performance during bypass-valve check

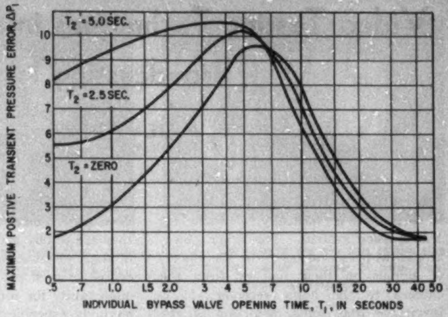

Fig. 18. Effect of bypass-valve checking procedure upon reactor vessel pressure transients

This study is not the final phase of the dynamic analysis of the particular nuclear power plant under consideration but, rather, is a step in the formulation of design characteristics and the understanding of the basic problems involved in its performance. This preliminary study points out several areas in which there is some question as to the assumptions made during the analysis of the system. In particular, two areas are being investigated in further detail for inclusion in a more comprehensive simulation of the system. These areas include a more refined thermal model of the reactor vessel and primary steam drum system in which the effects of the hydrodynamic coupling between the two vessels are included. This system includes the steam storage volumes in the dome of the reactor vessel and in the primary steam drum. The two storage volumes are coupled by a fairly long riser containing a mixture of steam and water which has the peculiar characteristic of being a relatively dense medium and at the same time being quite compressible. The effect of this coupled mass-spring system must be considered in the determination of the total power plant operation.

Another area in which additional information is needed is in the improvement of the reactor-void fraction map within the reactor core. In addition, the representation may become quite complex and include the hydraulic effects of the changing of flow velocities within the core channels as a function of the accumulation of the steam void density. Moreover, it may be necessary to go to a nodal model of the reactor in which both time and space dimensions of neutron flux are considered, rather than the calculated lumped space-time relationship with an assumed time function appended to compensate for the assumptions made in the original simulation.

The results of this study show the versatility of the analog computer technique in handling some of the extremely complex nonlinearities and product relationships which exist in large complex control systems. Although it would be feasible to program this problem for a digital type of analysis, much more data appears obtainable in a more reasonable time by using the analog computer techniques. The results are presented in such a form that a good appreciation of the physical picture of the real time performance of the system is obtained. In addition, the analog computer simulation may be adapted to form the heart of a power plant simulator, in which the outputs are used to drive the various meters and instrumentation equipment. Such a power plant simulator may be used as an operator training device so that experience may be gained in the operating characteristics of the reactor power plant long before the actual components are put in operation.

Video Testing Techniques in Television Broadcasting

A. STE-MARIE
NONMEMBER AIEE

A TELEVISION video transmission system is basically a waveform transmission system. The prime objective is the preservation of the waveforms of signals on their journey from the camera to the home receiver. It is inevitable that some distortion of the signal occur in any practical transmission path. The amount of distortion which is permissible is based not on physical measurements alone but on viewing tests by critical observers. Those physically measurable characteristics in which large variations cause no detectable difference in the quality of the received picture may be permitted large tolerances, while those to which the picture quality is particularly sensitive are permitted only small tolerances.

The following transmission parameters are usually taken into consideration:

1. Amplitude versus frequency characteristic
2. Phase delay versus frequency characteristic
3. Transient response
4. Differential gain and phase

Although a substantial amount of effort has been devoted to determining the effects of these transmission factors on picture quality, especially in color transmission, a great deal more work is required before the true significance of each parameter is known as well as establishing adequate correlation between them. More complete performance specifications are urgently needed for monochrome television systems and components.

The faithful reproduction of color pictures imposes yet more stringent requirements on video transmission systems. At the outset, the National Television Systems Committee recommended standards and tolerances dealing with several of the transmission parameters. These recommendations were eventually approved by the FCC (Federal Communications Commission). Certain of the tolerances specified in the color standards, although justified from the standpoint of ultimate picture quality, are difficult to attain in practice. Tolerances for other parameters are not specified.

New video testing techniques have been developed to meet the challenge although they are still by and large incomplete and in many instances lacking in the required degree of accuracy. There is plenty of opportunity for improved and simplified methods of specification and measurement. Test procedures should be standardized in order to insure greater convenience along with completeness, repeatability, and easy communication of the test results.

About 2 years ago the tolerances in the FCC color television standards were tentatively divided as follows: 60% for the transmitter equipment, 20% for the studio equipment, and 20% for the studio to transmitter link. At that time, no reference was made to the intercity network facilities. Several industry committees, including those of IRE (Institute Radio Engineers), the Radio-Electronics-Television Manufacturers Association, and the Canadian Radio Technical Planning Board, have been investigating this problem further, but progress has been slow to date. These same committees are also active in analyzing test equipment requirements and testing procedures.

Amplitude Versus Frequency

The amplitude versus frequency response of a video transmission system is a measure of the ability of the system to reproduce detail in the horizontal direction. It can be shown, assuming an ideal phase characteristic, that the maximum steepness of transitions in the picture and therefore picture sharpness is a function of the integral of the amplitude versus frequency response of the system, i.e., the area under the curve. Picture quality is not appreciably affected by variations of the shape of the amplitude versus frequency characteristic in the vicinity of the cut-off frequency, so long as the average rate of change in this frequency range is not altered. However, in the substantially flat part of the amplitude characteristic, comparatively small variations with frequency cause echo effects in the picture.

In color television, tests have indicated that critical observers would rate 1 or 2 db (decibels) amplitude variations in the region of the color subcarrier, with respect to low-frequency components, as "Impairment to picture but not objectionable." Even smaller tolerances must be used at low frequencies to keep smearing and streaking down to a tolerable level for both monochrome and color transmissions.

It is generally advisable to use a reduced input voltage for frequency response measurements, in order to prevent overload conditions or other nonlinearities in the equipment under test from interfering with the measurement. Special care must be taken when checking systems and/or components exhibiting peaks in the frequency response.

SINE-WAVE OSCILLATORS

Point-to-point sine-wave testing is by far the simplest and possibly the most precise method of measurement. It possesses the added advantage of providing for a complete coverage of the video frequency band. However, it is a time-consuming process and one that cannot readily be used to check the performance of systems containing keyed clampers. The point-to-point test method is recommended for applications where a high order of accuracy is desirable and when time permits.

MULTIBURST GENERATORS

The multifrequency burst generator, better known as the multiburst generator, produces a series of equal amplitude bursts of sine wave of various frequencies, usually extending from 0.5 mc (megacycles) to 6.0 mc. In addition, the output wave form includes sync and blanking pulses and a white-bar signal; Fig. 1.

For quick checks, discrete sine-wave bursts of known frequencies are usually sufficient to show at a glance the general nature of the amplitude versus-frequency characteristic. Test results are easy to tabulate and report. The test signal includes sync and blanking pulses and therefore will pass in the normal manner through the various television components and circuits. The multiburst test signal is especially well-suited for

---

Paper 57-666, recommended by the AIEE Television and Aural Broadcasting Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting, Montreal, Que., Canada, June 24–28, 1957. Manuscript submitted April 18, 1957; made available for printing July 9, 1957.

A. STE-MARIE is with the Canadian Broadcasting Corporation, Montreal, Que., Canada.

The author wishes to thank J. E. Hayes and J. Carlisle for their encouragement and valuable assistance, and Mr. Fournier for his contribution in assembling the test data and preparing the slides for this paper.

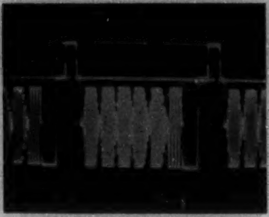

Fig. 1. Multiburst test signal. The sine-wave test frequencies are: 0.5, 1.5, 2.0, 3.0, 3.6, 4.2 mc

routine checks on systems. For this reason it has been recommended for television network tests by the Joint Television Network Committees, grouping the Canadian Broadcasting Corporation, the Trans Canada Telephone System and the Canadian National and Canadian Pacific Telegraphs; see Figs. 2–5.

Sweep Generators

Sweep generators provide a continuous display of the amplitude versus frequency response of the circuit under test. Sync and blanking pulses can be readily added to the swept sine-wave output of the generators. Combined with fixed-frequency markers, this test signal is as convenient as the multiburst test signal from the standpoint of tabulating, reporting, and comparing results. Swept signals are especially well suited for equipment and system alignment including equalizer adjustments, over-all studio system tests as well as routine checks on all video circuits; see Figs. 6–16.

Phase Delay

In television transmission systems, the times of transmission of all frequencies in the video spectrum should be substantially equal. The transmission time over a system is known as the phase delay or envelope delay and is expressed mathematically as the first derivative of the phase shift with respect to the frequency. If the phase is measured in radians and the frequency in radians per second, the phase delay will be in seconds.

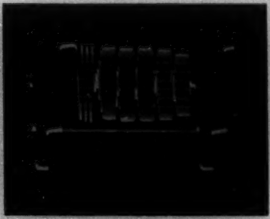

Fig. 2. Typical test result using the multiburst test signal. Circuit under test: local video channel

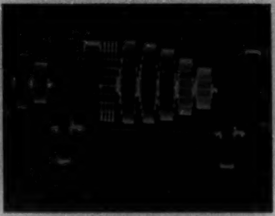

Fig. 3. Another test result exhibiting a 6-db drop in the amplitude response at 4.2 mc

The time of transmission of a single-frequency wave through a system is called the absolute phase delay or envelope delay of the system at that frequency, but it is not usually possible or necessary to measure this. The quantity that is of importance is the difference in phase delay or envelope delay between signal components of different frequencies.

In discussing phase-delay distortion in television transmission systems, we must differentiate between the parts of the frequency spectrum in which the distortion occurs. In the televised picture of a thin vertical line, for example, phase-delay distortion at the higher frequencies would be revealed by a displacement of the edges of the line and by one or more displaced images commonly referred to as ringing. But with a wider object, only its edges would be affected by phase-delay distortion at the higher frequencies.

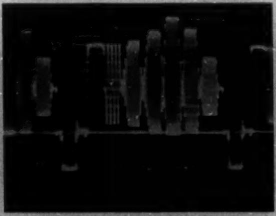

Fig. 4. Test signal as viewed at the output of an improperly aligned stabilizing amplifier. The response is overpeaked in the vicinity of 3.0 mc and falls off rapidly thereafter. There is also evidence of black compression interfering with the measurement

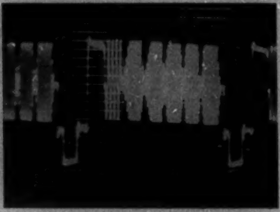

Fig. 5. Example of the a-c axis of the sine waves being shifted because of poor low-frequency response

Constant phase delay in a transmission system gives the best transient response possible for a given amplitude response. Delay distortion at the higher frequencies will also be accompanied by a corresponding decrease in the rate of rise of the transient response with a consequent loss in picture sharpness due to blurring of sharp edges. A phase-delay distortion of 0.1 μsec (microseconds) of the higher frequency components in a television signal is readily apparent, and in actual practice, the phase-delay distortion at the higher frequencies should not be allowed to exceed approximately ±0.5 μsec. Phase-delay distortions at the middle frequencies from about 200 kc upwards, affect the definition of a picture markedly. This type of distortion is better known as smearing; the impairment is a blurring of the vertical edges of objects in the televised scene and the whole picture looks as if it had been smeared along the horizontal axis. Finally, phase-delay distortions at the lower frequencies, from about 15 kc to approximately 200 kc, result in the most objectionable type of picture impairment, known as streaking.

It is quite certain that small delay distortions in the low and middle frequency band affect picture quality markedly,

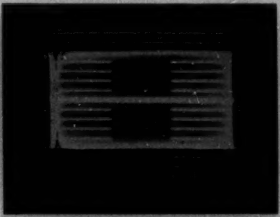

Fig. 6. Swap generator output waveform. (The single variable frequency marker is barely visible as a small pip located near the top right-hand corner of the display)

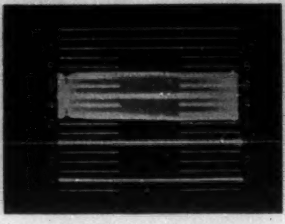

Fig. 7. Same test signal as in Fig. 6 but with added sync and blanking pulses

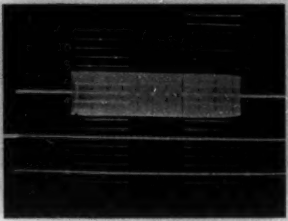

Fig. 9. Same test signal as in Fig. 8 but with added sync and blanking pulses

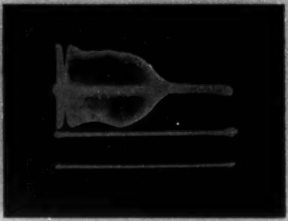

Fig. 11. Typical system test result. Circuit under test: over-all studio facility plus local video channel. Marker set at 4.2 mc

whereas they become of less importance as the upper frequency limit of the system is approached. Consequently, narrow tolerances should be placed on delay distortions in the low- and middle-frequency range.

In color television the subject of phase-delay distortion assumes additional importance because 1. misregistration of the luminance and chrominance signals in the reproduced color picture is an evident defect, 2. in receiving the color transmission on a monochrome receiver the compatibility will be impaired if the pattern resulting from the chrominance signals is not coincident with the corresponding luminance signal, and 3. abrupt delay variations occurring over rather small frequency increments in the upper portion of the video band can cause shifts in phase between various color components creating hue shifts.

It is difficult to measure relative phase delay to the required degree of accuracy. Most known methods of measurements apply only to the frequency range extending from approximately 500 kv upward. Phase-delay distortions occurring in the range from 15 kc to approximately 500 kc, cannot be measured conveniently at this time. This is indeed unfortunate since these distortions will cause impairments to the picture which are most objectionable in monochrome as well as in color transmission. It is the author's opinion, no matter what method of measurement is used, in order to insure maximum usefulness, the test signal selected should be a synthetic television signal; i.e., a test signal containing sync and blanking pulses.

Transient Response

The amplitude-frequency response of a monochrome system is geneally maintained fairly constant so as to assure a reasonable phase characteristic rather than to avoid a loss in picture detail. Although more important, the phase-frequency characteristic alone is not a complete measure of the waveform transmission capabilities of a system. A television transmission system is basically a waveform transmission system, i.e., a system in which it is important to preserve the waveforms of signals. Transmission performance is better expressed by the waveform responses to suitably chosen test signals because they can more directly be related to picture quality, even though, from a mathematical point of view the steady-state (amplitude and phase) and waveform responses are equivalent in that a full knowledge of either enables the other to be calculated. Square-wave testing was introduced early in television transmission work. Among the pioneers of waveform testing in television were Puckle in 1935 and Bedford and Fredendall in 1939 and 1942. However, progress has been slow and waveform testing and specifying has not yet become common at least on this side of the Atlantic. However, this is not true of several European countries, especially England, where waveform techniques have been developed and are now well established.

SINE-SQUARED PULSES

In the recent years, sine-squared pulses have been substituted for square waves. A sine-squared pulse has the property of containing relatively large amplitude components of frequency up to a certain frequency, and only small components of almost negligible amplitude above that frequency. If the half-amplitude duration of the pulse is equal to $1/2f$, the response is down 6 db at a frequency f. Further, the frequency spectrum is zero at $2f$. For example, if f is chosen as 4 mc (the nominal television bandwidth) the corresponding half-amplitude duration is 0.125 μsec. The spectral

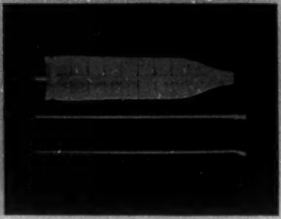

Fig. 15. Typical equipment test result. Equipment under test: stabilizing amplifier

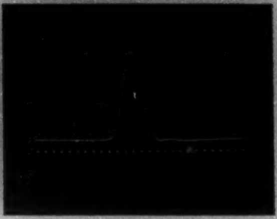

Fig. 17. Sine-squared pulse (half-amplitude duration: 0.125 μsec)

response of this pulse is 6 db down at 4 mc and is zero at 8 mc; see Fig. 17.

An ideal square wave intended for testing a system over the upper part of the frequency range generally produces a waveform response which includes a substantial amount of irrelevant information tending to obscure the relevant. The effect is minimized by using a sine-squared pulse, having an amplitude-frequency spectrum which falls away as rapidly as possible above the nominal upper cut-off frequency of the system under test. Furthermore, if the half-amplitude duration of the pulse is made $1/f$ or 0.25 μsec, its spectrum is down 6 db at 2 mc and is zero at 4 mc; see Figs. 18 and 19.

The particular merit of this latter pulse is that it is capable of being transmitted without distortion through an ideal low-pass system with an upper cut-off frequency of 4 mc. In other words, the response of a typical 4-mc television system to this pulse contains practically no irrelevant information. It is then especially well-suited for routine tests on such systems. However, these test waveforms and others can be used to advantage only if adequate correlation has been established between waveform response characteristics on the one hand and picture quality on the other. Ideally the performance specifications for any component or part of a system should be based on subjective picture appraisal determinations of the maximum amount of waveform distortion tolerable in a complete television system and subsequent allocation of fractions of this amount to eack link. In actual practice, due attention must be given to results known to be attainable with some regard to economy. Once the performance specifications are agreed upon, waveform responses can be evaluated at a glance. Suitable oscilloscope masks can be devised for this purpose. Among the features of sine-squared pulse responses usually specificed are the maximum allowable half-amplitude duration and the maximum tolerable overshoots and undershoots, leading, and trailing (Figs. 20–26).

Although wave-form techniques are remarkably simple and meaningful, there remains a serious drawback. Should the transient response fall outside the limits specified, it usually becomes necessary to revert to steady-state measurements in order to secure quantative data on the amount of amplitude and/or phase distortion present. This is so, mainly because, in the present status of the art, components and systems are specified throughout the industry in terms of steady-state responses and alignment procedures are based on this more conventional approach. However, the newly developed waveform synthetizing and waveform-correcting networks of the "time equalizer" and other types will allow one to operate directly on the waveform response. Another obstacle to a more rapid progress of waveform measuring techniques has been the difficulty of handling the computational problems of cascade connected links and networks. This difficulty has now been greatly overcome by the development of the time-series method.

Time series can also be used to advantage in the derivation of the steady-state characteristics from the transient response. Greater speed and convenience as well as a much higher order of accuracy can be achieved by this method. However, waveform responses secure direct information on the waveform transmission capabilities of the circuit under test. On the other hand, measurements of amplitude and phase versus frequency have little significance unless the results can be interpreted in terms of waveform

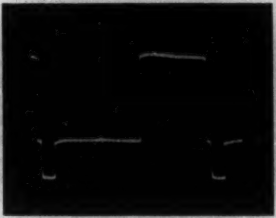

Fig. 23. Same as Fig. 22 but with 2-mc pulse

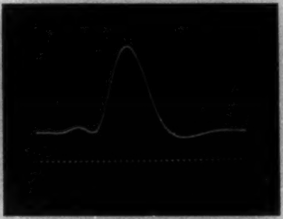

Fig. 26. Response of the same long-distance television network channel to the 2-mc pulse

responses. Therefore, for our needs, the derivation of the steady-state characteristics from the transient response is a matter of little more than purely academic interest.

WINDOW-TEST SIGNAL

Rectangular pulses, at field and line rates, are now in common use for checking the low-frequency transient response of television components and systems. A typical test signal is the "window" signal, so-called because it produces a white window on a dark background when displayed on a picture monitor; see Fig. 27. Originally developed to help locate streaking, the window-test signal will provide a ready measure of the transmission performance at the lower end of the video spectrum. It is an extremely useful tool in television transmission work especially in view of the lack of suitable methods of measurement of the amplitude and phase responses in that portion of the video spectrum. The window-test signal embodies sync and blanking pulses and can therefore be used to check the over-all as well as any part of the television system.

As was pointed out earlier, streaking is caused by transmission irregularities in the frequency region up to about 200 kc and will therefore be detected by the use of the window signal. Streaking is a typical television picture defect that affects almost equally both color and black and white signal transmission.

Distortions that cause streaking can occur in any part of the transmission system from the camera to the television receiver. Prevention of these defects required very close control of transmission characteristics in the lower frequency portion of the video band, see Figs. 28–30. A 5-degree phase shift or 1-μsec delay at the fundamental frequency will cause a tilt of approximately 24% in the window-test signal corresponding to an

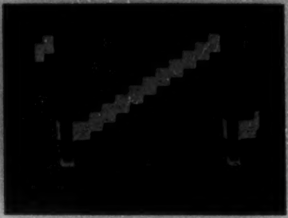

Fig. 32. Output of stairstep generator. Low-frequency exploratory signal plus high-frequency sine wave

intolerable amount of streaking in the transmitted picture. As a matter of fact, a 5% tilt will result in distortions readily noticed during normal picture transmission, and defects corresponding to as little as 2% tilt may be detectable under certain conditions. It is worth noting that while a 5-degree phase shift gives 24% tilt, the change in amplification that accompanies this in a normal resistance-capacitance coupled amplifier can be shown to be about 0.05 db.

Differential Gain and Differential Phase

The following definitions have been extracted from the IRE Standards on Television; definitions of Television Signal Measurement Terms, 1955. Differential gain: in a video transmission system, the difference in the gain of the system for a small high-frequency sine-wave signal at two stated levels of a low-frequency signal on which it is superimposed. Differential phase: in a video transmission system, the difference in phase shift through the system for a small high-frequency sine-wave signal at two stated levels of a low-frequency signal on which it is superimposed.

The term level is used here to define a specified position on an amplitude scale applied to a signal wave form. If the foregoing definitions are accepted, it is redundant to speak of differential gain distortion or differential phase distortion, since differential gain or differential phase is distortion. Both differential gain and differential phase are zero for an ideal transmission circuit. In monochrome television, differential phase has little significance if any. Differential gain, on the other hand, is a measure of the departure from linearity of the transfer characteristic of the transmission system. In severe cases of differential gain this form of distortion will result in either white compression or black compression or a combination of both. Small amounts of differential gain have but little effect on picture quality.

In color television transmission, it is an entirely different story. Since the transmitted luminance component and the chrominance components should be independent of each other, it is evident that the chrominance components must not be affected by the luminance. Otherwise, for example, as an actress walked from the dimly lighted edge of a scene to the brightly lighted center the color of her dress would change strangely. The color subcarrier signal component being transmitted by adding it to the luminance or monochrome component, it follows that the average luminance level determines the *a-c* axis of the subcarrier.

Therefore the desired independence of chrominance and luminance signals means that the change of gain of the subcarrier as a function of signal level, and likewise the change of phase, should be zero, in other words, the differential gain and the differential phase should both be zero. Differential gain will cause a change in saturation of the colors while differential phase will be responsible for a change in hue. Of the two types of distortion, the latter is obviously the more objectionable. The average viewer is usually critical of hue shifts, espcially when flesh tones and objects of readily identified colors are being reproduced. It is well known that a phase shift of about ±5 degrees at the color subcarrier frequency is readily detectable.

The definitions presented in the foregoing for differential gain and phase contain within themselves a suggestion as to a basic measurement technique. Differential gain and phase can be measured with the aid of a test signal having two essential components, a low-frequency "exploratory" signal of sufficient amplitude to explore the entire amplitude range of the system, plus a high-frequency sine-wave of relatively small amplitude superimposed on the exploratory signal. The

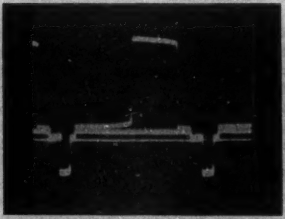

Fig. 29. Example of negative streaking. Amount of tilt: 6%

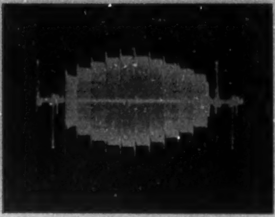

Fig. 37. Typical oscilloscopic display when both white and black compression are present

test signal should preferably be a synthetic television signal, containing synchronizing and blanking pulses, which can be passed through all normal transmission circuits; see Figs. 31 and 32. For differential gain measurements, the output of the equipment under test is applied to an oscilloscope scanning at half the line frequency and through a high-pass filter which will remove the low-frequency exploratory signal and leave the subcarrier oscillations, see Figs. 33–35.

At this time, we should like to stress an apparent deficiency in the definitions of differential gain and phase quoted previously. As will be remembered, the definitions refer to the difference in gain and phase of the system for a small high-frequency sine-wave signal at two stated levels of a low-frequency signal on which it is superimposed. Whatever these two stated levels are, say blanking and reference white levels, the measured amounts of differential gain and differential phase at these two levels may yield an incomplete and inaccurate picture of the transmission performance of the circuit under test. As a matter of fact, it can be shown that under certain conditions, relatively small amounts of differential gain and phase can be measured between two stated levels of the low-frequency signal while it is evident that large amounts of differential gain and phase actually exist when the over-all amplitude range of the picture signal is taken into consideration; see Figs. 36 and 37.

The authors would like to recommend the following alternate definitions. Differential gain: In a video transmission system, differential gain is the maximum difference in gain of the system for a small amplitude high-frequency sine-wave, the a-c axis of which is varied from blanking to peak-white level by means of a low-frequency exploratory signal on which it is superimposed. Differential phase: In a video transmission differential phase is the maximum difference in phase shift through the system for a small amplitude high-frequency sine wave the a-c axis of which is varied from blanking to peak-white level by means of a low-frequency exploratory signal on which it is superimposed.

Differential phase can be measured by means of a high-pass filter coupled to a synchronous detector, in which the phase of the subcarrier component of the test signal is compared with that of a continuous reference subcarrier signal. A cathode-ray oscilloscope can be used as a null indicator at the detector output, and phase differences between the unknown and the reference subcarrier can be measured with a calibrated phase shifter. The reference subcarrier is usually extracted from the test signal itself.

Calibration of Test Equipment

The need for adequate calibration of the test equipment cannot be too strongly emphasized. Voltmeters and oscilloscopes must be checked for voltage calibration. This may be done conveniently, using a suitable substandard voltmeter, specified to the required order of accuracy. More important still is the calibration of the amplitude versus frequency response of the oscilloscope. A useful device for the calibration of oscilloscopes is the Western Electric type *70B* transmission measuring set. It is a thermocouple operated power measuring meter designed to operate in the frequency range from direct current to 10 mc. The accuracy in terms of absolute power expected at 0 db on the meter scale is ±0.1 db, while the differential accuracy over the entire frequency range is within +0.1 db. Such an instrument is not only extremely useful for the calibration of oscilloscopes, but will permit making direct point-to-point measurements on individual amplifiers, equalizers, cables, and other system components whenever a higher degree of accuracy may be required.

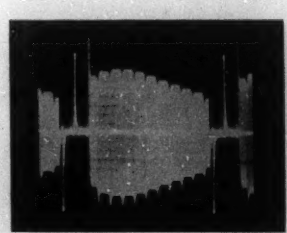

Fig. 36. Typical oscilloscopic display when both white and black compression are present

The frequency calibration of multiburst generators, sweep generators, and sine-wave oscillators should be checked with adequate care. One will understand that test results can hardly be correlated if the test frequencies cannot be ascertained within reasonable limits. Frequency calibration can usually be performed to a sufficient degree of accuracy without recourse to expensive and bulky frequency measuring equipment.

Oscilloscopes used for waveform testing especially sine-squared pulse measurements must be carefully calibrated along the time axis. Marker generators used for this purpose should preferably be crystal controlled.

In all, it is well to remember that even the best of test equipment is susceptible to changes in performance and drifts in calibration, if not the occasional failure. For this reason, the calibration of the test equipment must be checked regularly, in order to insure accurate and reliable test results.

Statistical Encoding for Text and Picture Communication

W. S. MICHEL
NONMEMBER AIEE

SUGGESTIONS have been made from time to time for reducing the transmission time or bandwidth required for the facsimile transmission of text or pictorial material by representing it by a description which has low redundancy. This paper presents an investigation of the channel capacity required for various types of copy, using one such description, based on one-dimensional differential coordinates together with statistically matched encoding. A binary digital transmission channel is assumed throughout. Only black and white copy is considered. A written or printed message is assumed to consist of a 2-dimensional array of resolution elements, called dots, whose number determines the definition. Since a definition of 0.01 inch is widely accepted as satisfactory for facsimile reproduction of black and white copy, this figure, corresponding to almost a million dots for an $8^1/_2$- by 11-inch typewriter-size sheet, is used throughout.

Dots, Dot Groups, and Patterns

A piece of copy may be reproduced at another location if a tabulation is available specifying for all the resolution elements or dots whether they are black or white. Such a tabulation may be called a "description" of the copy. The description need not necessarily proceed dot by dot and we shall distinguish among three schemes of description, i.e., three types of "alphabets." These are in terms of dots, dot groups, and patterns respectively. The first and most elementary specifies blackness or whiteness for each dot individually. In the second, configurations of dots, i.e., dot groups, are specified. For example, the description may take the form of a statement of the number of black, or white, dots occurring in successive continuous runs measured along one co-ordinate, with the other held constant;[1] or it may have more elaborate forms. In the third scheme, patterns of black or of white dots are the alphabet items and the description of the copy is in terms of these patterns and their locations. Patterns, as defined here, are assumed to include only a limited number of select configurations characteristic of the specific class of material for which the system is designed, but not all the possible configurations. A system based on a pattern alphabet cannot, therefore, handle copy in which patterns occur which it does not "recognize." On the other hand, the dot system, and the dot-group system as here defined, can recognize any and all copy, subject only to the limits set by the resolution.

Depending on the alphabet chosen and, of course, the subsequent coding used, the channel capacity required for average copy may be large or small. The actual information content of the copy is in general lower than this, the difference being the redundancy. For maximum efficiency of information transfer the alphabet and the coding should be such that there is a minimum of redundancy.

In practice, the efficiency that can be attained is usually limited by cost considerations. Thus the choice of an alphabet must be scaled to one's ability to build readers and printers able to operate in terms of the alphabet; and the degree of statistical matching may have to fall short of ideal in order to keep translator complexity down. Readers for recognizing printed characters can vary from fairly simple to rather elaborate computer-like designs, depending on the constraints one is willing to put on such factors as shape or position. More sophisticated systems operating with whole words or word groups would probably be more complex, unless messages are readily identifiable and small in variety, such as greetings telegrams. The ideal system which would recognize each piece of copy as a unit, and send only one code character for it, appears of forbidding complexity at this time, except for simple cases.

At the other end of the spectrum from these sophisticated approaches is the familiar commercial facsimile. Here each dot is, in effect, specified individually, and the reading and printing processes may be regarded as consisting simply of the identification and production of black dots, one at a time. Efficiency tends to be low, each piece of material taking the same transmission time per unit area. The differential co-ordinate description to be discussed uses a simple kind of dot-group alphabet which lends itself to a fairly straightforward analysis. Combined with even simple forms of statistical encoding this description makes it possible, in general, to specify an $8^1/_2$- by 11-inch page by considerably fewer than a million binary digits.

Differential Co-ordinate Encoding

Command Structures

In differential co-ordinate or "run-length" encoding, the number of black, or white, dots occurring in continuous runs of

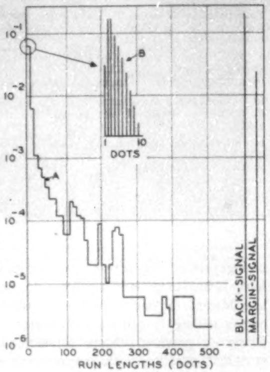

Fig. 1. Probability distribution of run lengths in a 300-word pica-typewritten letter

one color along scan lines is measured by a scanner. Such a scanner may be thought of as operating like a television or facsimile scanner modified so that whenever it encounters a transition from black to white or from white to black it sends to the encoder a count representing the number of dots between this and the previous transition. Upon receiving such a signal, the encoder translates it and subsequently sends the appropriate digital code character over the line, possibly via a storage device.

Table I. Portion of Pica-Tailored Code

Item	Code Symbol
Black	00
2 dots	010
3 dots	011
4 dots	100
5 dots	1010
6 dots	1011
Margin (also empty line)	11000
7 dots	11001
1 dot	11010
8 dots	11011

Table II. Binary Digits per 8½- by 11-Inch Page

Type of Copy	Binary Digits
Empty page	5,500
Simple drawing, Fig. 3(B)	50,000
Grid with 2-inch spacing	60,000
300-word pica letter	100,000
Circuit schematic, Fig. 3(A)	120,000
Page filled with pica type	300,000
Grid with 1-millimeter spacing	400,000
Page filled with 8-point type	700,000
Two black and one white dot alternating horizontally	3,000,000

In general, each code character represents a command to the receiver. Such commands may be specifications of run lengths or of operational routines such as "print the following length black," or "move to the next line." The ensemble of different commands pertaining to a specific scheme of description will be called a "command structure."

Various command structures are possible within the differential co-ordinate family. These may differ in such secondary features as the method of distinguishing black from white lengths, or in the way advantage is taken of the fact that black lengths always follow white, and vice versa. In the course of the present work, it was found that several such variations gave rise to differences in efficiency of the order of only 10%. Therefore, results are quoted only for one specific command structure. This has the following characteristics:

1. Black and white runs of the same magnitude have the same code characters.
2. The receiver assumes runs to be white, unless they are preceded by a special code character which indicates otherwise.
3. Single black dots occurring, for example, in the vertical legs of typed characters are not sent. Instead, the receiver is engineered to print a black dot automatically after each white run.

Typical Probability Distributions

The probability distribution on which a code is based should be that which will be encountered, on the average, in the copy to be transmitted. No account is taken here of the error statistics of the transmission medium, or of the relative seriousness of errors in the various code characters. For a general system, it appears to be more important to provide good matching for text than for drawings, since text is likely to contain finer detail, and hence requires greater channel capacity, as measured in the differential co-ordinate description. Therefore, most of the results here presented are derived for a "pica-tailored" language. This means a statistical encoding based on the probability distribution of commands as encountered in pica-typewritten material, in the form of an English-language business letter.

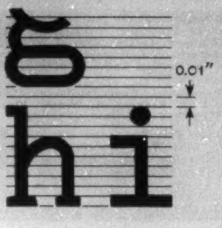

Fig. 2. Enlargement of pica-typewriter characters

This distribution exhibits a high peak at very short run lengths, and subsequently a rapid drop off, as shown in curve *A* of Fig. 1 in which the probability

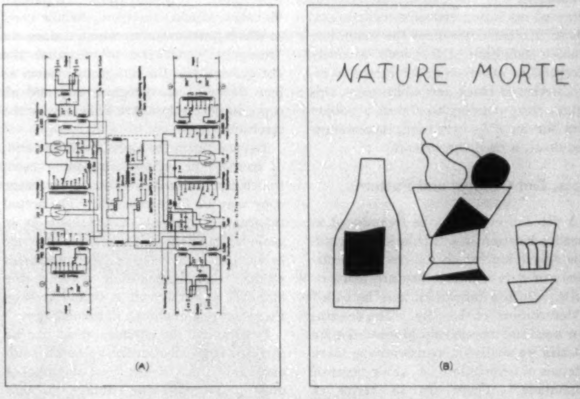

Fig. 3. Two types of drawings

A—Circuit schematic
B—Simple drawing, for which channel capacities are given in Table II.
Frames indicate size of 8½- by 11-inch sheet

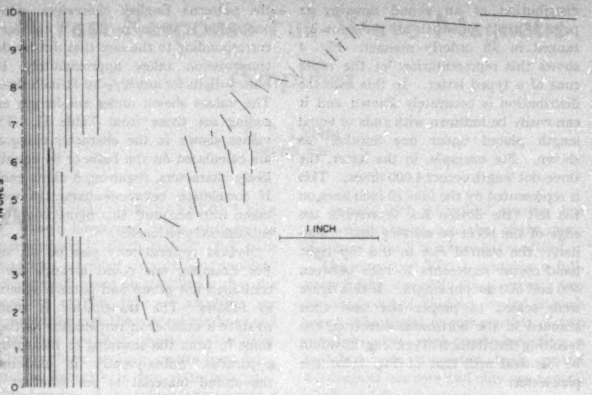

Fig. 4. White run lengths in a 300-word pica-typewritten letter

per command, averaged over 10 commands at a time, is plotted as a histogram. Curve *B* represents the probabilities of the first ten commands, plotted individually. Minor peaks occur in the probability curve at the lengths corresponding to the distances from the edge of the paper to the left margin, to paragraphs, etc. The exact nature and position of these will vary with the particular spatial arrangement of the copy; but their effect is negligible since they represent low probability totals.

Throughout this work, the scanning is assumed to proceed across the page at right angles to its longer dimension. The actual measurements of run lengths were made on enlargements of the 26 lower-case letters of a pica typewriter. For run lengths associated with single letters and for run lengths occurring between adjacent letters, the measured values were weighted in accordance with the well-known monogram and digram frequencies, respectively, of the English language.[3] For runs between alternate letters, such as between the top of the *b* and the top of the *t* in *but*, trigram tables[4] give some of the required probabilities of occurrence. The remaining values were determined by actual count through several pages of typewritten material. A typical enlargement of pica-typewritten letters is shown in Fig. 2.

For drawings or mixtures of text and drawings, the longer runs become relatively more probable. Black dots occur in a more random manner than in type so that an exponential distribution of run lengths might be expected. Other arguments lead to a hyperbolic distribution. In any event, short runs still tend to predominate over the long ones. Moreover, as mentioned above, the number of run lengths per unit area is smaller, so that run-length encoding is advantageous even with the less accurate statistical matching resulting from using the pica-tailored code for drawings.

CHOOSING A CODE

The encoding problem consists of setting up a code so that the expected length per code character is a minimum. A well-known procedure for this is the so-called Shannon-Fano code and its modification by Huffman.[3-6] The results presented here are based on a Shannon-Fano encoding of the command structure described previously using a smoothed form of the probability distribution shown in Fig. 1. Because of the large alphabet involved, a close match is possible, yielding an actual average length per code character only about 1% higher than the ideal length, i.e., the entropy. Correlation between successive run lengths is not taken into account in this encoding. The initial portion of the code book is shown in Table I. Code-character lengths are found to vary from 2 binary digits for the black signal to 20 digits for the signal corresponding to the maximum run length.

RESULTS FOR TYPEWRITTEN TEXT

With the code described in the previous section, approximately 100,000 binary digits are found to be required for the description of a 300-word pica letter. In view of the good statistical matching obtained, this also represents the lower bound on the number of binary digits required to express the average page in terms of individually coded run lengths. The same figure may also serve as an upper bound on the actual information content, which must therefore be less than 100,000 bits.

The foregoing results may be extended to other kinds of type by qualitative considerations. For example, it is readily seen that the required number of binary digits will be approximately proportional to the number of characters, and further that the effects of differences in spatial arrangement will, in general, be small.

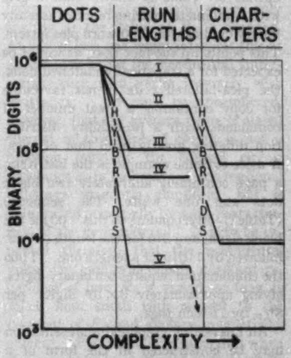

Fig. 5. Channel capacities required for various types of facsimile transmission, versus complexity of instrumentation

I—Solid page of 8-point print
II—Solid page of pica type
III—300-word pica letter
IV—Simple drawing
V—Empty page

Table III. Categories for Encoding Picture Material

	Dots	Dot Groups	Patterns
Required channel capacity	generally high: same for all types of material	variable; lower for simple or favored material	very low for special material
Versatility	unlimited	unlimited	handles special material only

Narrower characters will tend to require a similar, and wider characters a somewhat higher binary digit rate per character than pica.

RESULTS FOR DRAWINGS

The differential co-ordinate description of drawings would be expected to exhibit features differing from that for text. For example, one would expect a greater fraction of long runs, as has been pointed out, but a smaller total of runs. Different drawings will not, in general, present such high uniformity in their differential co-ordinate descriptions as different pieces of text. Therefore, it is not as easy to make general and yet fairly precise statements about binary digit rates for drawings as for text. However, individual drawings often have features which make a reasonable estimate possible by inspection or by a few quick measurements. One such feature which is often found is the occurrence of the same run length many times, as in a rectangular block.

Channel capacities required for some types of drawings are listed in Table II in terms of the total number of binary digits. These figures are based on the pica-tailored code. It may be noted that the schematic, Fig. 3(A), while much more complicated than the simple drawing Fig. 3(B), requires only about twice as many binary digits, chiefly because its many small run lengths match the code more closely.

Comparison of the fourth and seventh entries of Table II shows that a grid with 1-millimeter spacing requires as many binary digits as four 300-word pica letters. This points up the fact that, as would be expected for a statistically matched code, the pica-tailored code is not favorable for copy containing a great number of commands with a probability distribution differing greatly from that of pica. A more extreme example is the last item, a page containing alternately two black dots and one white. The sequence (Table I) corresponding to this is 00 for the black signal and 010 for the length of two, followed by 11010 for a length one. Thus the combination requires ten binary digits, giving approximately 3×10^6 digits per $8^1/_2$- by 11-inch page.

An interesting graphical representation may be constructed in the form of a drawing having the same run-length distribution as an actual drawing or page of text, but with all the runs arranged in an orderly manner. Fig. 4 shows this representation for the white runs of a typed letter. In this case the distribution is accurately known and it can easily be redrawn with runs of equal length placed under one another, as shown. For example, in the letter, the three-dot length occurs 4,000 times. This is represented by the four 10-inch lines on the left (the dotted line represents the edge of the sheet or starting line); similarly, the slanted line in the top right hand corner represents 15 runs between 400 and 500 dots in length. If this figure were scaled to proper size and then scanned in the horizontal direction, the resulting distribution of run lengths would be identical with that of Fig. 1 for the pica letter.

Discussion

While this study suggests that run-length encoding is capable of yielding substantial reduction in transmission time as compared with dot-by-dot transmission, a number of facts should be pointed out. First, in run-length encoding, an error in one binary digit tends to propagate and hence is more serious than in the dot-by-dot description where it merely changes the polarity of one dot. Second, the present study is limited to a very simple form of differential co-ordinate encoding. Correlation between successive runs is not taken into account and the encoding is one dimensional, no advantage being taken of the very pronounced regularities in the vertical direction exhibited by many types of copy.

In Table III the various approaches to the encoding of picture material which have been discussed or touched upon are reviewed. As one proceeds from left to right, required channel capacity decreases, but instrumentation complexity increases. Versatility is unlimited in the first two categories in that all possible combinations of black and white dots are permitted; in the pattern category it is limited to the allowed patterns. Fig. 5 shows semiquantitatively the different channel capacities required for certain types of material for the specific case where the dot groups are run lengths and the patterns English characters. Only one value is shown in the dot category, corresponding to the fact that dot-by-dot transmission takes approximately 10^6 binary digits for any $8^1/_2$- by 11-inch sheet. The values shown under run-length encoding are those from Table II. The values shown in the character category are calculated on the basis of 64 equally likely characters, requiring 6 digits each. If correlation between characters were taken into account[6] this figure could be substantially reduced.

Hybrid systems may also be set up. For example, one could arrange for a combined dot group and pattern scheme as follows. The transmitter is made to store a number of run lengths as they come in from the scanning or measuring apparatus. Subsequently it examines the stored material to see whether it makes up one of a number of predetermined patterns. If so, a special code symbol for the pattern is sent; if not, the code symbols for the stored run lengths are sent routinely. An alternative example, a hybrid scheme falling between the dot and length categories would be provided by applying to facsimile a coding procedure discussed by Shannon.[6] This is suitable for a source with an alphabet of two items of very unequal probabilities and might be applied to facsimile by making black and white dots the two items. While run-length encoding is only a first and simple step in this spectrum of possibilities, the results obtained are believed to be encouraging.

A Fast-Response Full-Wave Magnetic Amplifier

G. E. LYNN
MEMBER AIEE

A FEW RECENT PAPERS[1-3] have been concerned with analyses of conventional, single-ended, full-wave magnetic amplifier circuits (or "doublet" amplifiers[4]) based on the theory that the reactors of this type of amplifier are coupled through the control windings and that this coupling results in feedback. The feedback, in turn, causes time delay and an increase in the volts/volt gain. The purpose of this paper is to present a novel circuit which clearly demonstrates the existence of the feedback phenomenon and to offer, for the magnetic amplifier design engineer, a mathematical treatment of this phenomenon both in the time domain and the frequency domain.

Circuit Operation

If feedback does occur in doublet amplifiers, it should be possible, by decoupling the reactors during appropriate periods, to produce a circuit identical with a doublet amplifier except that feedback is absent. To this end, the circuit of Fig. 1 was devised. Use of the bridge circuit avoids the coupling of the reactors through the load circuit which occurs in the doubler and center-tapped circuits. The circuit presented in the second figure of reference 1 achieves the same end result; i.e., a fast-response full-wave amplifier, but does so by feeding back a volt-second area which is invariant with respect to the signal. Such a method introduces some complications which the circuit of Fig. 1 avoids.

To achieve circuit simplicity, the magnetic amplifier of Fig. 1 obtains its gating voltage from a square-wave generator. This eliminates the need to cascade clipping circuits to derive, from a sinusoidal source, a synchronous square wave with which to drive the switched-mode[5] transistors used. Conclusions drawn from the use of this circuit are applicable to circuits with sinusoidal sources, but some wave shapes, e.g., that of the resetting current, will be somewhat modified.

The circuit of Fig. 1 contains a full-wave bridge magnetic amplifier with two identical control windings wound on each core. The signal circuit consists of two parallel paths, each path including a switched-mode transistor, both control windings of one core and only one control winding of the other core.

In discussing circuit operation, the following simplifying assumptions will be made:

1. For the core material used, the ratio of remanent flux density to maximum flux density is unity, $B_r/B_m=1$.
2. The rectifying elements in the load circuit are ideal; i.e., zero conduction in the reverse direction and zero voltage drop in the forward direction.
3. The resistance in the windings of the reactors is negligible.
4. When applied to winding N_{G1} or N_{G2}, the magnitude of E_{ac} is just sufficient to drive the flux of the respective reactor from negative to positive saturation in one half-cycle of supply frequency.
5. With respect to a half-period of the supply, the switching time of the transistors is negligible; i.e., V_1 and V_2 open or close instantaneously as the polarity of the square-wave generator changes.
6. When operating as a closed switch, the voltage drop across the transistor is zero; when operating as an open switch, conduction through the transistor is zero.
7. The time during which "back-firing" of the rectifiers occurs is negligible with respect to a half-period of the supply.
8. The output impedance of energy sources is negligible.

The square-wave generator supplies voltage to transformer T_1 and to the load circuit of the magnetic amplifier. The center-tapped secondary of T_1 supplies base-drive current to switched-mode transistors V_1 and V_2 during alternate half-cycles, closing V_1 while opening V_2 and closing V_2 while opening V_1. When the polarity of the generator output is as shown in Fig. 1, reactor L_1 is in its gating half-cycle. Transistor V_1 is acting as a closed switch and the signal voltage, E_s, is applied to the series combination of N_{F1}, N_{S2}, N_{S1}, and R_S. In addition, during this time, transistor V_2 is acting as an open switch and the path containing winding N_{F2} is therefore an open circuit. Under these conditions, the voltages induced in windings N_{F1} and N_{S1} by the application of gating voltage to winding N_{G1} cancel each other as far as their effect on the control circuit is concerned. Because of this cancellation, the effective control circuit consists only of E_s, N_{S2}, and R_S throughout the time that the output of the square-wave generator has the polarity shown. When the polarity changes, reactor L_2 starts to gate, transistor V_1 is switched to its open condition, transistor V_2 is switched to its closed condition, the voltages appearing across windings N_{S1} and N_{F2} are in series opposition, and the effective control circuit consists only of E_S, N_{S1}, and R_S. It is now obvious that, during the reset half-cycle of each reactor, there is only one energy source to produce reset. That source is E_S. As is well known, the average volt-second area appearing across the terminals of any one winding of a reactor is zero in steady state; however, by switching windings N_{F1} and N_{F2} in and out of the control circuit at the proper intervals, each reactor presents a d-c load to the signal source.

STATIC GAIN

In Fig. 2, data are presented which show the dependence of load voltage, E_L, on E_S for various values of R_S. It can be seen from Fig. 2 that the slope of the transfer characteristic (representing the incremental volts/volt gain) varies only slightly as the value of R_S is changed. At first glance one might interpret this as an indication that the incremental volts/-ampere-turn gain varies inversely with resistance. It must be remembered, however, that the average value of signal current in this type of circuit is not a function only of the control circuit resistance as in half-wave or conventional full-wave magnetic amplifiers, but is determined principally by some characteristic of the core material. It is to be expected therefore that the incremental volts/volt gain will remain constant regardless of how R_S is varied, so long as R_S is kept small with respect to the quotient of E_S and average magnetizing current. Fig. 2 also illustrates that when the restriction on allowed values of R_S is less valid, a change in incremental volts/volt gain is discernible. For instance, changing R_S by a factor of two from 250 to 500 ohms decreases the slope by about 1.2%, whereas changing R_S by the same factor from 2,500 to 5,000 ohms decreases the slope about 11%. This indicates an effective average resistance

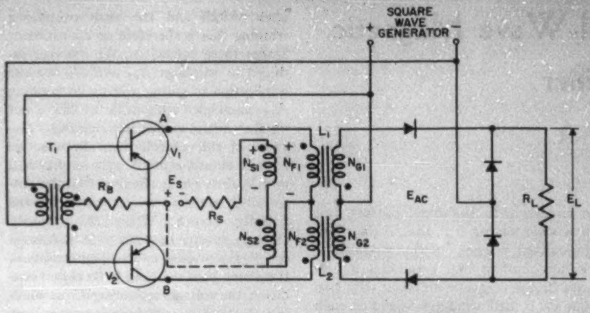

Fig. 1. Circuit of fast-response full-wave magnetic amplifier

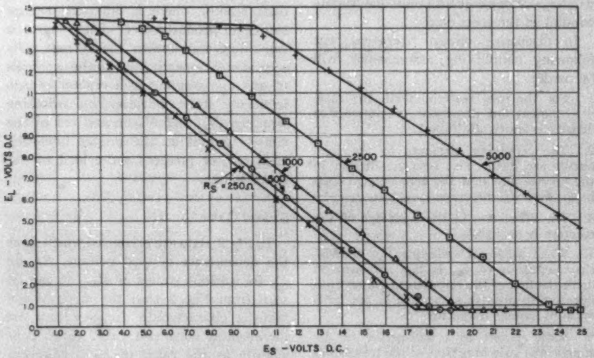

Fig. 2. Static transfer characteristics of fast-response amplifier (R_s as parameter)

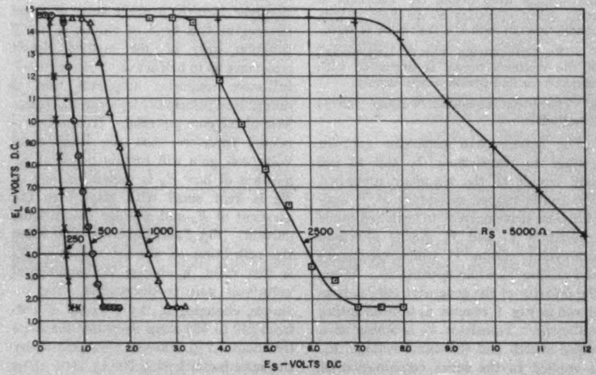

Fig. 3. Static transfer characteristics of doublet amplifier (R_s as parameter)

of between 25,000 and 30,000 ohms for the reactors.

Of additional interest in Fig. 2 is the variation, as R_S is changed, in the magnitude of signal voltage which must be applied before an appreciable amount of reset is obtained. This variation clearly indicates the existence of threshold ampere-turns[4] or a knee on the effective flux-current loop. The existence of this knee indicates that some minimum current must flow to initiate reset but, after establishing this exciting current, the amplifier is essentially a voltage-controlled device (for low values of R_S). The fact that the magnitude of this knee is proportional to the value of R_S only for larger values of R_S is attributed to the presence of some resistance other than that ascribed to R_S in the experimental control circuit, probably in the signal source used.

For purposes of comparison, the volts/volt characteristics of a conventional full-wave magnetic amplifier are shown in Fig. 3 for the same values of R_S as were used in obtaining the data of Fig. 2. The changes to the circuit of Fig. 1 to obtain a doublet amplifier are simply opening points *A* and *B* and connecting a jumper as shown by the dotted line. The effect of the presence in the control circuit of the voltage across the control winding caused by gating of each reactor is clearly evident from a comparison of Figs. 2 and 3 with proper regard to the different abscissa scales used. The incremental volts/volt gain for the same R_S is greater for the doublet amplifier in all cases. In addition, the incremental volts/volt gain of the doublet amplifier is roughly inversely proportional to the value of R_S as would be expected from consideration of the amplifier as an ampere-turn controlled device.

A significant aspect of a comparison between results obtained with the circuit operating as a fast-response amplifier and then as a doublet amplifier is that the average voltage observed across R_S is the same for both configurations, at least as long as the value of R_S remains low. A few points taken with R_S equal to 500 ohms in the fast-response configuration are shown as heavy dots in Fig. 3. The abscissa would read "average volts across R_S" for these points, the ordinate remaining the same. These data show that the volts/ampere-turn gain remains the same for both circuit types.

Dynamic Response of the Doublet Amplifier

To establish the existence of a phenomenon which can properly be called "feedback," it is necessary to show that,

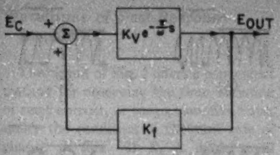

Fig. 4. Block diagram representing the 2-winding doublet amplifier

not only is the static gain affected, but the time response as well. The data of Figs. 2 and 3 have proved that coupling between the two reactors in the control circuit increases the volts/volt gain. Experimental evidence showing the fast-response nature of the circuit of Fig. 1 will be presented later and it is well known that the conventional bridge circuit does not exhibit this characteristic. However, a mathematical treatment showing why, with feedback, the response to a step input changes from a pure "dead-time" to a more or less exponential change in output will be of interest.

Johannessen has published[3] the block diagram of Fig. 4 and, using difference equations, has derived, from this diagram, an approximate volts/volt transfer function in terms of the turn ratio and various resistances. To obtain this result, an operating flux-current loop with vertical sides was postulated. While the method may be extensible to conditions where the slope of the sides of the loop is noninfinite, the mathematics would probably become unwieldy. For this reason, the treatment presented here will be expressed in terms of circuit gains only, without regard to how these gains are obtained. The treatment is rigorous and the only assumption made about the operating flux current loop is that B_r/B_m is unity. This assumption makes it possible to avoid considering voltages induced in the control circuit of the gating reactor when it is supposedly saturated. A further assumption will be made about the circuit operating conditions. It will be assumed that the circuit is biased to the upper knee of the left flank of the operating flux-current loop. This assumption in no way detracts from rigor but makes it possible to consider the output change proportional to the input without introducing another delta in the notation.

In Fig. 4, the forward path contains a block which represents the basic half-wave amplifier having a static volts/volt gain, K_v, and a dead-time, π/ω. In servomechanism notation, this block can be expressed mathematically as $K_v e^{-\pi s/\omega}$. The feedback path contains a volts/volt gain (which is less than unity), K_f. The voltage fed back is summed with the signal voltage, E_c, as shown. It must always be borne in mind that with no input, E_{out} will be a maximum. However, the voltage fed back through the gating core is proportional to the change in output voltage, ΔE_{out}, and not to the output voltage magnitude.

In the treatment, the notation below, following Johannessen as closely as possible, will be used:

E_c = control voltage averaged over a half-cycle of supply
E_{out} = output voltage averaged over a half-cycle of supply
e = base of Naperian logarithms
K = closed-loop voltage gain
K_f = feedback voltage gain
K_v = forward voltage gain
s = complex frequency variable
ω = frequency of supply, radians per second

Ignoring the frequency dependent terms for the moment, the following may be written directly from Fig. 4.

$$\Delta E_{out} = K_v(E_c + K_f \Delta E_{out}) \tag{1}$$

from which can be derived

$$\Delta E_{out}/E_c = K_v/(1 - K_v K_f) = K \tag{2}$$

which is the closed-loop voltage gain.

An objection might be raised at this point that, since a half-wave amplifier resets on one half-cycle and has an output on the succeeding half-cycle, no output voltage is available to be fed back during the reset half-cycle. Fig. 4, however, represents a doublet amplifier in which the resetting core is represented by the forward transmission and the gating core by the feedback path. Each core then alternately serves in each capacity and the gating core provides the output voltage in the proper time period.

If we assume a step input of E_c at a time when reactor L_1 is starting its reset half-cycle, no change in output voltage will appear for one half-cycle of the supply. Since both cores have previously been at saturation, no voltage appears on the windings of reactor L_2 during this half-cycle. In the next half-cycle, reactor L_1 will gate and the average value of the output voltage during this half-cycle will be reduced by an amount proportional to the voltage, E_c. Observe that the behavior of reactor L_1 during the first full cycle is identical with what it would have been if the reactor were in a half-wave circuit.

We may write:

$$\Delta E_{out(1)} = K_v E_c \tag{3}$$

where the numerical subscript indicates the half-cycle in which the parameter is measured. During this first gating half-cycle, the change in output voltage, which is equivalent to the amount of voltage which was absorbed by the reactor prior

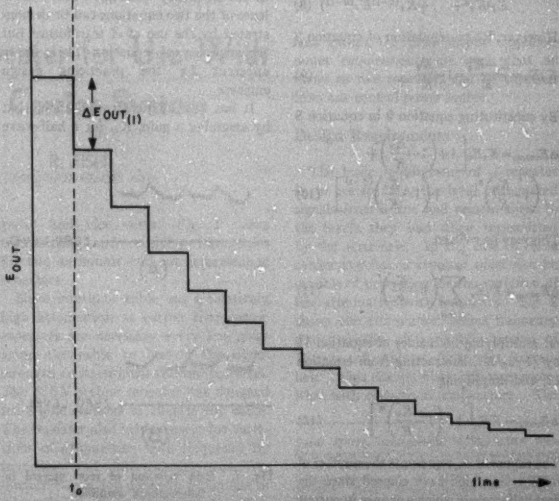

Fig. 5. Time domain response of doublet amplifier to step input applied one half-period before t_0

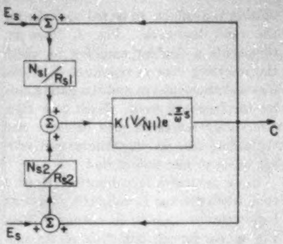

Fig. 6. Suggested block diagram representation of multi-input doublet amplifier

to firing, is reflected into the control circuit and adds to E_c in producing reset of reactor L_2. If K_f is the gain of the transfer of volt seconds from one reactor to the other through the control circuit

$$\Delta E_{out(2)} = K_g(E_c + K_f \Delta E_{out(1)}) \quad (4)$$

Substituting equation 3 in 4

$$\Delta E_{out(2)} = K_g(E_c + K_f K_g E_c) = K_g E_c(1 + K_f K_g) \quad (5)$$

Similarly

$$\Delta E_{out(3)} = K_g(E_c + K_f \Delta E_{out(2)}) \quad (6)$$

$$= K_g E_c(1 + K_f K_g + K_f^2 K_g^2) \quad (7)$$

whence, by extension

$$\Delta E_{out(n)} = K_g E_c\,(1 + K_f K_g + K_f^2 K_g^2 + \ldots + K_g^{(n-1)} K_f^{(n-1)}) \quad (8)$$

However, by manipulation of equation 2

$$K_f K_g = \frac{K - K_g}{K} = 1 - \frac{K_g}{K} \quad (9)$$

By substituting equation 9 in equation 8

$$\Delta E_{out(n)} = K_g E_c \left[1 + \left(1 - \frac{K_g}{K}\right) + \left(1 - \frac{K_g}{K}\right)^2 + \ldots + \left(1 - \frac{K_g}{K}\right)^{(n-1)}\right] \quad (10)$$

This may be written

$$\Delta E_{out(n)} = K_g E_c \sum_{r=0}^{n-1} \left(1 - \frac{K_g}{K}\right)^r \quad (11)$$

or, multiplying both sides of equation 11 by $(1-K_g/K)$, subtracting from equation 11, and simplifying

$$\Delta E_{out(n)} = K E_c \left[1 - \left(1 - \frac{K_g}{K}\right)^n\right] \quad (12)$$

The exponent, n, represents the number of half-cycles which have elapsed since the first half-cycle in which a change in output occurred following the step change in E_c. If π/ω is the time duration of a half-cycle, $n = t\omega/\pi$ where t is time measured from the beginning of the first half-cycle. Substituting for n, equation 12 can be expressed as a function of time and further simplified to

$$\Delta E_{out} = K E_c(1 - e^{-at}) \quad (13)$$

where

$$a = -\omega \ln(1 - K_g/K)/\pi$$

or

$$\Delta E_{out}/E_c = K(1 - e^{-at}) \quad (14)$$

Equation 13 is recognized as the familiar exponential usually used to represent the time delay of magnetic amplifiers. Since $\Delta E_{out(n)}$ is defined as an average quantity (averaged over π/ω), equation 13 has no meaning except at points where $t\omega/\pi$ is equal to an integer. The proper representation, then, is a series of steps, constantly decreasing in step magnitude as shown in Fig. 5.

By inclusion of the frequency dependent terms in equation 2, the following is obtained

$$\frac{\Delta E_{out}}{E_c} = \frac{K_g e^{-s\pi/\omega}}{1 - K_f K_g e^{-s\pi/\omega}} \quad (15)$$

This expression in the frequency domain is equivalent to equation 14 in the time domain (with the appropriate restrictions on allowable values of $-at$ in the time domain, and if a step input is postulated in the frequency domain). The equivalence of the two equations can be demonstrated by the use of Z transforms[6] but the meaning of equation 14 is more apparent for the practicing design engineer.

It has been demonstrated, then, that by assuming a gain, K_g, for a half-wave amplifier, a higher gain, K, is obtained for the doublet amplifier, but at the expense of an exponential form of time delay in addition to the "dead-time" inherent in all self-saturating magnetic amplifiers.

THEORY LIMITATIONS

The preceding work has been concerned with an amplifier which has only two windings, a control winding, and a gating winding. The positive feedback voltage from the gating reactor adds directly to the signal voltage in the control circuit and the feedback voltage gain is a function of the control circuit resistance. However, magnetic amplifiers are frequently used as summing amplifiers because of the isolation which can be achieved by use of multiple input windings. The representation of the amplifier as a volts/volt gain device in these instances seems somewhat awkward since a reactor cannot sum, but discriminates, voltages.[7] For this reason, a representation similar to that in Fig. 6 would seem preferable. In this diagram, the basic half-wave amplifier is assigned a gain in volts/ampere-turn and the individual winding turns and control circuit resistances are indicated in separate blocks. Unfortunately, in contrast to a 2-winding reactor, the volts/ampere-turn gain of the basic amplifier block will no longer be constant as N^2/R is varied, but will be a function of the resistance values chosen and the square of the turns of the individual windings. In view of this limitation, Fig. 6 does not seem to be a satisfactory final solution and further investigation of block diagrams suitable for use in these applications is indicated before detailed analysis with this type of representation can be attempted.

Waveforms of Fast-Response Amplifier

The circuit of Fig. 1 offers a convenient method for observing the time variation of reset current, or magnetomotive force, under the condition of constant rate of change of flux. If R_s is made small (25 ohms or less) the voltage across R_s is of the order of 1/10% of the applied voltage and may be said to represent the current required to reset a reactor from a voltage source. An oscilloscopic presentation of this voltage is shown in Fig. 7. A recent paper[8] presents the core-reset function under just such conditions obtained by other methods but does not include a picture of the current for comparison with Fig. 7.

It can be seen in Fig. 7 that there is a surprisingly large difference between the shapes of the currents required to reset the two cores. The two cores were chosen on the basis of identical readings obtained from a constant current flux-reset type core tester. On the basis of average output values, the cores seem to be well-matched even under the conditions imposed by the circuit of Fig. 1, but the time variations of the currents in achieving the same amount of reset are hardly equivalent. Neither core exhibits the constant current characteristic which would be required under the assumption of a vertical-sided flux-current loop.

To illustrate the fast response nature of the circuit of Fig. 1, Fig. 8 is presented. The circuit used in obtaining these pictures differed in some respects from the circuit presented in this paper, principally in that a sinusoidal source was used in place of the square-wave generator and a square-wave generator was used to supply E_s. It can be seen that full response to the step change in signal is always achieved by, at latest, the second gating half-cycle following the step change, not counting the half-cycle in which the change is initiated. This is the best response obtainable with a magnetic amplifier since the reactor which is gating at the time of the signal change will respond completely to the change in its next gating half-cycle, but the reactor which is resetting at the time of the signal will only respond completely in its second gating half-cycle following the change.

Conclusion

A full-wave fast-response magnetic amplifier circuit has been presented which can be used to substantiate the theory that a two-winding doublet amplifier can be represented by the block diagram of Fig. 4. The limitation of Fig. 4 to 2-winding amplifier representation has been indicated and a possible path for future investigation for a more general diagram has been suggested. The restriction of signal current to the current flowing through a reactor resetting under the desired N^2/R conditions suggests that the circuit can be used as a flexible investigational tool to explore core properties.

A Transistorized Repeater for Use With the 45BN Cable Carrier System

V. BABIN
ASSOCIATE MEMBER AIEE

R. FISH
ASSOCIATE MEMBER AIEE

THE REPEATER described in this paper is a part of the *45BN* carrier telephone system. This system transmits and receives 24 voice channels over two pairs in a nonloaded exchange or toll cable. It is a member of a family of miniaturized carrier systems using many interchangeable subassemblies.[1,2,3] The complete family of type *45* carrier equipment provides carrier transmission over open-wire cable and radio circuits.

Type *45BN* equipment uses single-side-band suppressed carrier modulation and operates in the frequency range from 40 to 140 kc (low group) in one direction and from 164 to 264 kc (high group) in the other direction. A terminal that transmits the low group receives the high group and vice versa. Fig. 1 shows transmitting and receiving frequencies for two terminals without intermediate repeaters.

Since multipair cable has a relatively high attenuation at carrier frequencies, repeaters are necessary every few miles along the cable to restore the signal strength to its original transmitted level. The *45BN* system repeater was designed for 8-mile sections of 19-gage toll cable. The repeater also helps correct for variations of attenuation with frequency by inverting and interchanging the frequency bands for opposite directions of transmission from the repeater (frequency-frogging).

By the use of transistors for all amplifiers except the final output amplifier, power requirements are such that as many as five repeaters can be supplied from one central power source.

Design Requirements

The basic requirement of a repeater is to accept the low-level attenuated signals from a line and restore them to the levels they had when transmitted by the terminals. In the case of cable carrier systems, a repeater must also be capable of correcting for the variation of line attenuation with frequency. Fig. 2 shows the attenuation versus frequency characteristics of an 8-mile section of 19-gage toll cable at 46 degrees Fahrenheit. This characteristic will vary somewhat with changes in temperature. The

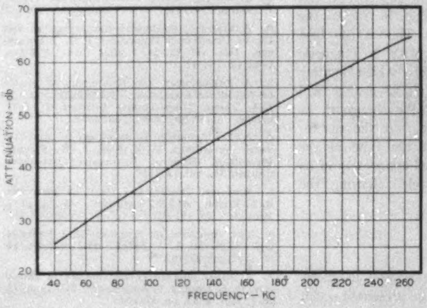

Fig. 2. Frequency versus attenuation curve for 8 miles of 19-gage toll cable. Temperature is 46 degrees Fahrenheit. Attenuation is higher at higher temperatures and lower at lower temperatures

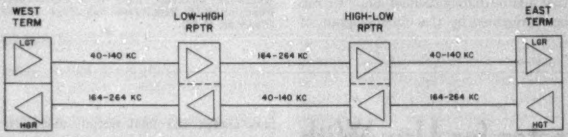

Fig. 3. Block diagram showing interchange of frequency bands by frequency-frogging repeaters

basic design requirement of the *45BN* repeater was to compensate for the effect of the attenuation characteristic on the high- and low-frequency bands transmitted by the system.

Since the attenuation characteristics vary with the temperature, regulation must be provided to adjust the gain of the repeater to maintain a constant output signal level with varying input signal level. The regulator action must be slow enough to give any system failure alarm time to operate in case of total loss of signal. Otherwise, the gain would increase too fast and amplification of noise and crosstalk would prevent the alarm from operating.

Because of the relatively short distances between repeaters, an economic advantage could be realized by feeding power remotely to repeaters. Power supplies then would not be needed at every repeater location. This would require low power consumption for each repeater, in itself, an economic advantage.

Since outdoor cabinets would, in many instances, be used to house the repeaters, the repeaters should be as small as possible to minimize the size or number of cabinets required. In addition, the repeaters must be capable of operating in ambient temperatures ranging from −40 to +60 C (degrees centigrade).

In practice, not every repeater section can be exactly 8 miles of 19-gage cable. Therefore, provisions must be made for the repeater to "see" the electrical characteristics of this design section even when the actual section differs in length or type of cable.

The *45BN* system is designed to operate in the same cable with Western Electric types *N* and *ON* systems. In some cases Western Electric *N* repeaters have been used with *BN* systems. To maintain the flexibility of application for types *45BN*, *N*, and *ON*, it was desirable that the *BN* repeater be electrically and physically interchangeable with the type *N* repeater.

Design Approach

As shown in Fig. 2, the repeater would require a gain of 64 db (decibels) in the high-group direction (the transmission loss at 264 kc) and a gain of 45 db in the low-group direction (the transmission loss at 140 kc). Equalization must correct the 19-db slope in the low group (26 db at 40 kc to 45 db at 140 kc) and the 15-db slope in the high group (49 db at 164 kc to 64 db at 264 kc). The high gain and equalization requirements could be eased considerably by using a frequency-frogging repeater.

A frequency-frogging repeater transposes the frequency bands for both directions of transmission. As the bands for both directions of transmission pass through the repeater, they are translated and interchanged to the portion of the frequency spectrum occupied by the other. The channels within the bands are also inverted in their order in the frequency spectrum. A frequency-frogging repeater can be a low-high repeater or a high-low repeater. That is, it can either receive the low groups from both directions and transmit high groups, or it can receive the high groups from both directions and transmit the low groups. In practice, low-high and high-low repeaters alternate along the cable between terminals. A block diagram of a *45BN* system with two such repeaters is shown in Fig. 3.

As a result of the interchange and inversion of channels, channels that suffer the greatest attenuation in the high group, suffer the least attenuation in the low group. For example, the channel transmitted in the 260- to 264-kc slot in the high group falls in the 40- to 44-kc slot in the low group. Therefore, the gain at each repeater need only equal the average loss between 40 and 264 kc, or 46 db. This is almost the requirement for low-group transmission only.

Frequency-frogging also makes the system almost completely self-equalizing as shown in Fig. 4. The residual slope amounts to about 2 db per repeater section. This is far easier to correct than the 19-db slope that occurs in the low group or the 15-db slope that occurs in the high group.

In addition to reducing the amplification required for individual repeaters,

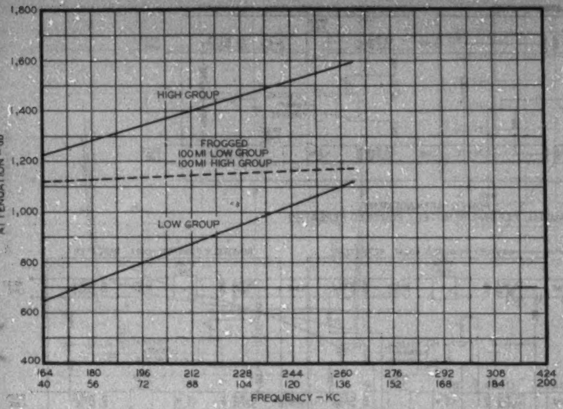

Fig. 4. Losses in 200 miles of 19-gage cable showing equalizing effect of frequency-frogging

frequency-frogging reduces run-around crosstalk. This is the crosstalk which arises through the high-level output of one repeater being coupled to a tertiary pair. The crosstalk signals are transmitted along the tertiary pair and then coupled to the low-level input of the repeater or to the inputs of adjacent repeaters. Since the frequency band transmitted by a frequency-frogging repeater differs from the frequency band received, these crosstalk signals will be out-of-band to the directional filters at the inputs.

Considerable advantage in maintenance and spare parts requirements could be realized if one repeater unit could be used interchangeably for either high-low or low-high operation. Therefore, the general design aimed at a circuit which could be changed from one method of operation to the other by no more than a minor adjustment.

The small size and low power requirements of the *45BN* repeater pointed to the use of transistors. Therefore, the development approach was based on a completely transistorized circuit. Earlier experience had shown that transistors could serve many of the functions of vacuum tubes with longer life expectancy and less power consumption.[3] It seemed natural to apply those advantages to repeaters which might be located at remote sites where minimum attendance and low power consumptions are desirable.

Laboratory investigation showed that transistors could be used in all the required circuits with one exception. This exception was the output stage of the power amplifier. The amplifier not only had to be a broad-band amplifier covering the frequency range from 40 to 264 kc, but also had to have power-handling capabilities similar to the Western Electric *408A* vacuum tube. It was at first assumed that the cost of a transistor amplifier of this type would be within economic limits. However, no single transistor was found that would consistently fulfill these requirements.

The final design of the repeater includes two vacuum tubes: one for the output stage for each direction of transmission. But the use of transistors in all other circuits of the repeater allows remote power feed to as many as two repeaters in tandem on each side of a locally powered repeater. This means that a power source is required only at every fifth repeater location.

Operation

Fig. 5 is a block diagram of the *45BN* repeater. The repeater may be connected for either low-high or high-low operation by means of threaded coaxial connectors at the front of the unit. When arranged for low-high operation, channels from the west in the 40- to 140-kc band enter the repeater through the input transformer and receiving span pad. This band then passes through the slope adjust network where 4 db of negative slope is introduced. It then passes through the 140-kc low-pass filter where unwanted high-group crosstalk (from the outputs of this and other repeaters) is removed.

The 40- to 140-kc band modulates the output of a 304-kc 2-stage transistor oscillator. The 304-kc carrier and the 40- to 140-kc input band are balanced out in the modulator. The output of the modulator then contains the two principal bands of 164 to 264 kc and 344 to 444 kc. A band-pass filter selects the 164- to 264-kc band and rejects the other.

By the time it reaches the output of the band-pass filter, the signal has been attenuated approximately 14 db: 4 db in the slope equalizer and 10 db in the modulator and filters. The 24-channel band is then amplified 60 db (46 db above the received level) and transmitted to the line.

The amplifier consists of three sections: (1) a 19-db fixed-gain single-stage transistor amplifier; (2) a 1-db, ±8 db, single-stage transistor regulating amplifier; and (3) a 40-db fixed-gain output amplifier consisting of a transistor pre-

amplifier and a vacuum-tube output stage.

For regulation, a portion of the output signal is picked off the output transformer, amplified and rectified, and then passed through a d-c amplifier and time-delay circuit. The output of the d-c amplifier heats a thermistor in the feedback loop of the regulating amplifier. Changes in signal level vary the thermistor resistance to control the feedback loop.

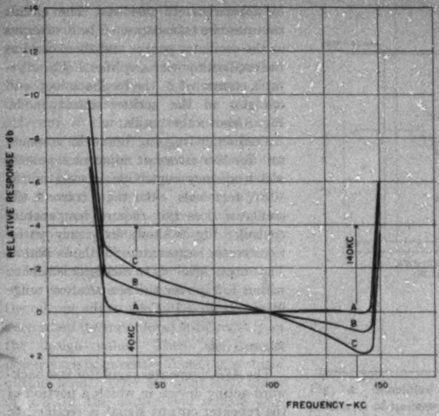
When the repeater is connected for high-low operation, the signal path through the modulator-filter-slope equalizer section is simply reversed. The incoming high group passes through a 164- to 264-kc band-pass filter which removes unwanted low-group crosstalk. This band then modulates the 304-kc signal from the oscillator. The principal outputs are a 40- to 140-kc band and a 468- to 568-kc band. A low-pass filter selects the lower of these. The 40- to 140-kc band undergoes about 2-db negative slope change in the slope equalizer and is then amplified and passed on to the line. The output is readjusted from a +12-dbm (db referred to 1 milliwatt) pilot for the high group to a +3-dbm pilot for the low group. This adjustment is made through a screwdriver-adjusted potentiometer. The potentiometer is easily reached at the front of the unit.

The process for either high-low or low-high operation is identical for both directions of transmission. The amplifier and regulator are flat over the entire band from 40 to 264 kc.

The new repeater meets the frequency response, noise, and intermodulation requirements for the Lenkurt type *45BN* systems as well as for the Western Electric types *N* and *ON* systems. Therefore, the *45BN* repeater will work equally well on any of the three systems.

Power Requirements

The *45BN* repeater requires slightly less than 100 ma (milliamperes) at 120 volts. No separate filament battery is needed. The two 20-volt filaments operate in series across the 120-volt supply. The 80-volt drop supplies part of the voltage required by the transistors



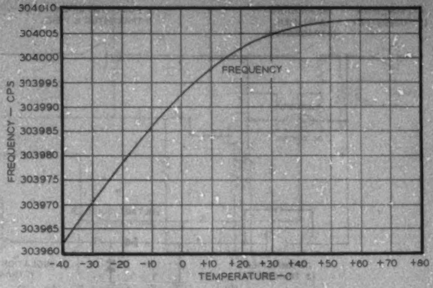


Fig. 9. Oscillator frequency versus temperature

Fig. 7 (left). Slope characteristics for the three settings of the 45BN repeater slope equalizer

so that very little power is wasted. Voltage of either polarity with respect to ground may be used.

Both input and output transformers are tapped with simplex leads. Through these leads, remote d-c power may be fed over the cable pairs used for carrier transmission. Fig. 6 shows several remote power-feed arrangements.

Remote power feed to two adjacent repeaters requires a power supply only at every third repeater. For this arrangement, +130 volts and −48 volts are necessary. These are voltages found in most telephone offices where −48 volts is required for telephone switching and +130 volts is standard for electronic equipment. Each *45BN* repeater has a rheostat to drop the applied voltage to the 120-volt value so that other voltages such as +130 volts and −130 volts may be used for remote power feed.

Even though power is fed over cable pairs whose resistance may vary due to temperature changes, no voltage regulation is required. The repeater tends to be self-regulating. In hot weather, an increase in cable resistance tends to decrease the voltage available at the remote repeater. But the accompanying increase in transmission loss in the cable requires more gain in the repeater. Under this condition, the regulator (and thus the entire repeater) draws less current through the increased cable resistance and the voltage at the repeater remains nearly constant. Under normal conditions, the voltage at the repeater remains constant within ±1 volt.

Power can be fed to two repeaters in tandem by using +130 and −130 volts. Tandem power feed reduces the requirements to only one power supply for every five repeater locations. In this type of operation, the voltage-compensating feature which has been described is not fully achieved because the second repeater draws power through twice the length of cable as before. For this reason, it is recommended that maximum repeater spacing be reduced to 7.8 miles when tandem power feed is used. In addition, the combination of extremely high temperature (such as desert locations) and long system length should be avoided.

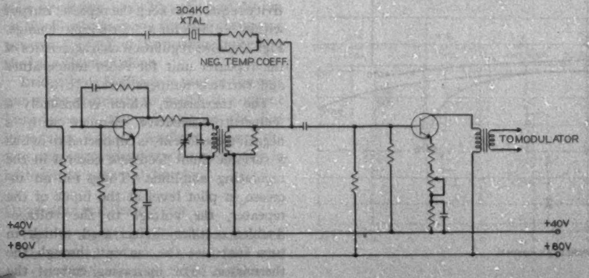

Fig. 8. Oscillator circuit which supplies the 304-kc frogging-frequency to the modulator

Circuit Description

Slope Equalizer

In an 8-mile repeater section, a low group will have about 4 db more slope than a high group. Or, taking the average of the two groups as the nominal slope, the low group has 2 db more than nominal and the high group has 2 db less than nominal. For proper operation of the frequency-frogging process, the two slopes should be equal. Therefore, it is necessary to remove 2 db of slope from received low groups and add 2 db of slope to received high groups. To do this, slope is not added to the received high group but is subtracted from it after it has been translated to a low group. This accomplishes the same purpose and allows a single network to perform both functions.

Since all repeater sections are not of the same length, the received groups will not always have the exact slope stated in the foregoing. To allow for minor deviations, two additional networks are included. These may be connected into the circuit by a screwdriver-operated switch on the face of the repeater unit.

Typical slope characteristics for the three settings are shown in Fig. 7. The *A* position gives a flat slope and the *C*

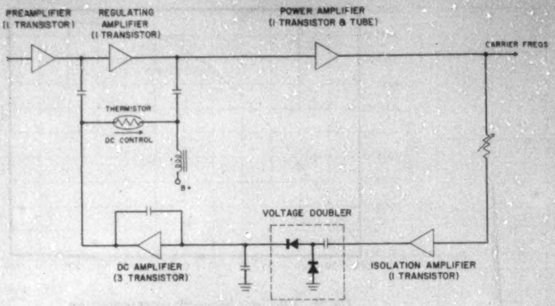

Fig. 10. Block diagram of regulator circuit

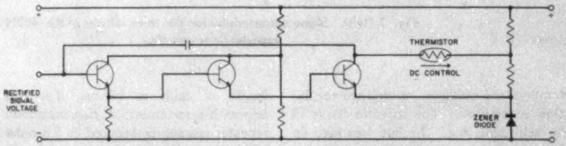

Fig. 11. Schematic of d-c amplifier

position gives −4 db of slope. The normally used *B* position gives −2 db of slope. Thus, adjustments may be made for slope deviations ±2 db from normal. The three positions give equal loss at the pilot frequency so that adjustments may be made without disturbing the output level of the repeater.

When necessary, larger slope deviations are compensated for by artificial lines. A slight negative bulge is introduced into the slope network to cancel the average bulge in the transmission characteristics of each repeater section.

Oscillator

The oscillator supplies the translating or frogging frequency, a nominal frequency of approximately 304 kc. The circuit contains two transistors. The first serves as the oscillator proper and the second as the oscillator power amplifier. The crystal is connected in the feedback loop and operates in the series-resonant mode. Fig. 8 shows the oscillator.

Frequency-frogging tends to compensate for like errors at adjacent repeaters and frequency correction is used in the 45*BN* terminals. For these reasons, the oscillator does not require temperature control. Fig. 9 shows frequency variations versus temperature for the oscillator. The output level of the oscillator is held to within ±5% over the temperature range from −40 to +70 C.

Regulator

The *45BN* repeater regulator is a backward-acting device in which a portion of the repeater output signal is rectified to control a thermistor resistance in the feedback loop of an earlier stage. Fig. 10 is a block diagram of the circuit.

The small portion of the power amplifier output is applied to a voltage-doubler rectifier through an amplifier which isolates the nonlinear rectifier circuit from the output circuit. This prevents the distortion generated in the rectifier from being applied to the line. The output of the rectifier is applied to a 3-stage d-c amplifier which multiplies the current to the proper value for control of the thermistor resistance.

The d-c amplifier consists of two cascaded grounded-collector transistor amplifiers followed by a grounded-emitter amplifier. Fig. 11 is a schematic of this circuit. The capacitor connected in the feedback loop over the three stages provides the necessary time delay in repeater regulation. On the average, the time delay will prevent the repeater gain from changing more than 1 db in the first 10 seconds after signal failure. The zener diode in the emitter lead of the final d-c amplifier provides the stiffness or sensitivity required to keep the repeater output within ±1.5 db for a ±8-db input change. Fig. 12 shows regulation characteristics of the repeater unit for room temperature and extreme temperatures.

The thermistor, which is basically a temperature-sensitive element with a negative coefficient, is connected to act as a variable-shunt feedback control in the regulating amplifier. Thus, for an increase in pilot level at the input of the repeater, the voltage to the voltage-doubler rectifier is increased, which in turn increases the current through the thermistor. For increasing current the thermistor resistance decreases, thus pro-

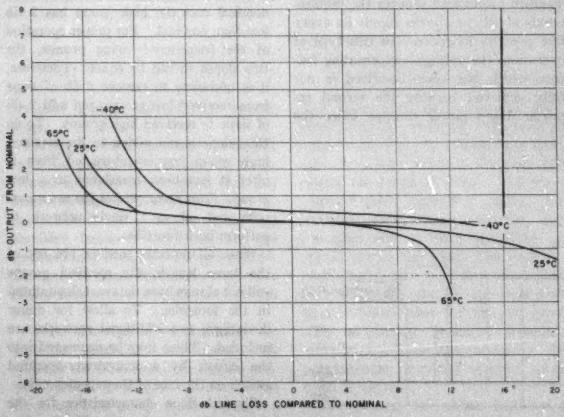

Fig. 12. Regulation characteristics of 45BN repeater for various temperatures

viding more feedback in the regulating amplifier and consequently reducing the gain of the stage.

The regulator circuit is voltage- rather than power-sensitive. This means that the regulator setting will be slightly different if the repeater is used with Western Electric *N* carrier which has 12 pilots, even though the total power of the 12 pilots is equal to the power of the single *45BN* pilot. For this reason, a continuously adjustable control rather than a strapping option has been provided to obtain the different output levels required for high-low or low-high operation.

Further, the continuous control makes the output adjustable to the correct level even when the input level is different from the design value. Thus, the output power variations center about the nominal output level. Over an input level range of ±8 db, the output will remain constant within ±1.5 db at any temperature within the design range of −40 to +60 C.

Power Amplifier

Fig. 13 is a schematic of the power amplifier. The input stage uses a transistor in the grounded-emitter configuration. The transistors in this and the preceding stages that amplify the carrier signals are high-frequency units. These are necessary to obtain wide-band frequency response. The alpha cutoff frequency of these transistors is above 5 megacycles.

Transistors are ideal for low-level stages such as these. Large savings in d-c power are possible. The transistors in these stages operate at a maximum power dissipation of 23 milliwatts. However, in addition to the power dissipated in the transistor, power is required to stabilize the transistor for temperature extremes. In some cases, this will be of the order of the power applied to the transistor itself. However, a comparison of the total power with the power required for a vacuum tube operating with 20 volts and 50 ma on the filament, shows that the transistor power is only 5% of the power required by the tube filament alone.

Bridge-type feedback is used in the output stage primarily to match the output impedance of the repeater to the line impedance. Loop feedback over the two stages provides distortion reduction in addition to gain stabilization.

Over-voltage Protector

Fig. 14 shows a simplified schematic of the method of tandem power feed used for the *45BN* repeater. The resistances represent the d-c resistance of the cable.

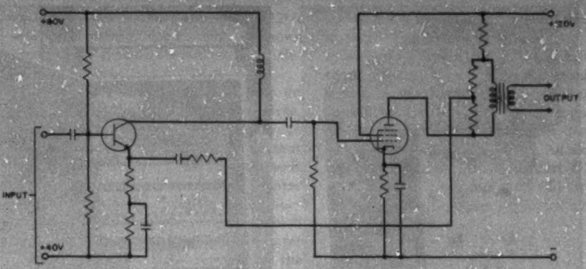

Fig. 13. Schematic of power amplifier

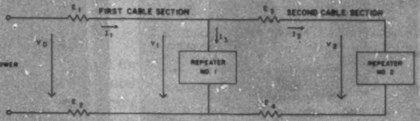

Fig. 14. Simplified schematic of tandem power feed

As can be seen, the voltage at each repeater is dependent on conditions at the other repeater. If a failure occurs at repeater no. 2, so that it draws no current, the voltage at repeater no. 1 may rise to approximately 170 volts. To prevent damage to the repeater unit from such failures, an overvoltage protector is incorporated in the *45BN* repeater.

There are a number of ways in which damaging voltages could occur. The most likely occurrence would be a filament failure or removal of a tube or repeater. A cable break would be another cause. The overvoltage protection circuit is designed to prevent damage to repeaters under these abnormal conditions. Overvoltage protection will not normally be required at a locally powered repeater point.

Fig. 15 is a simplified schematic of the d-c power distribution in the *45BN* repeater. The overvoltage protector consists of a 40-volt zener diode, *CR3*, and its bias resistor, *R4*, and a p-n-p power transistor. The diode provides a reference voltage slightly less than 40 volts that is applied to the transistor base. The transistor emitter is tied to the repeater 40-volt bus and the collector is connected to *B*−.

When the emitter potential is less than 40 volts, the power transistor draws no current, and the overvoltage protector has no effect in the repeater circuit. During abnormal conditions, such as the afore-mentioned, the emitter attempts to rise above 40 volts. It then draws sufficient current to offset the increase in voltage. The overvoltage protector maintains the 40-volt bus within 10% of normal for the most abnormal change. It thus protects transistor circuits and tube filaments from damage by bleeding extra current when the repeater voltage becomes high.

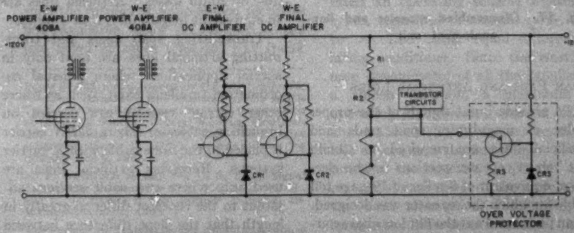

Fig. 15. Simplified schematic of d-c power distribution

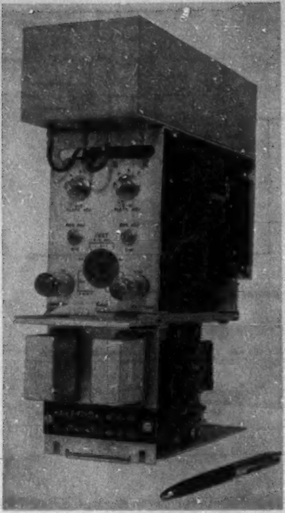

Fig. 16. Assembled repeater and line equipment unit

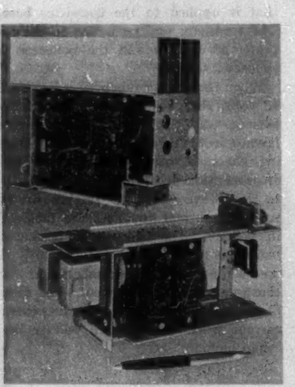

Fig. 17. Disassembled repeater and line-equipment unit

Span Pads and Artificial Lines

To provide input signals of the proper order of magnitude, span pads and artificial lines are required to "build out" short repeater sections to the electrical equivalent of 8 miles of 19-gage toll cable for which the repeater was designed. Span pads build out the flat loss characteristic of the line, and artificial lines build out the slope characteristic.

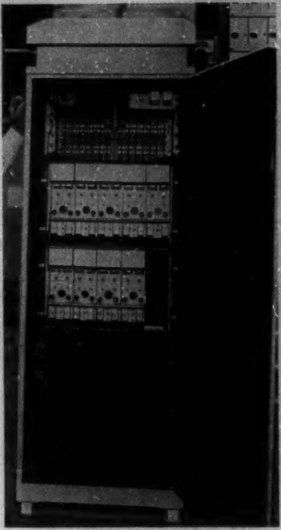

Fig. 18. Nine 45BN repeaters and their line-equipment units installed in cabinet for pole-mounting

The most common requirement is for receiving span pads. Therefore, each repeater is equipped with variable span pads in both recieving branches. These pads may be strapped for any loss from from 0 to 30 db in 2-db steps. The pads are on the equipment side of the line transformer so that their resistance will not decrease the power received over the cable pairs. This is especially valuable when tandem power feed is used.

Although seldom required, space is provided in the repeater for mounting transmitting span pads and both transmitting and receiving artificial lines. Transmitting span pads have 4-, 8-, 12-, 16-, or 20-db losses. Artificial lines are in equivalent lengths of 1, 2, or 4 miles.

Transmitting span pads and transmitting artificial lines are used only in special applications where unusual coordination problems exist, such as where other carrier systems are carried on branching cables or where *45BN* carrier is placed in the same cable with *K* carrier systems. Receiving artificial lines are used only where two cable sections adjacent to the repeater differ so greatly in length that the slope difference between the two cannot be cancelled by the repeater slope adjustment.

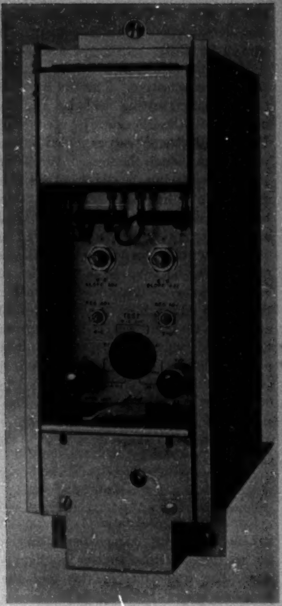

Fig. 19. A 45BN repeater unit mounted in adapter for use in Western Electric type N repeater racks

Mechanical

The complete *45BN* repeater consists of two units: a repeater unit and a line-equipment unit. The line-equipment unit may be replaced with a mounting adapter if the repeater is to mount on Western Electric type *N* repeater shelves. The repeater and line-equipment units are shown assembled and disassembled in Figs. 16 and 17.

The repeater unit contains the oscillator, filters, modulators, slope equalizers, amplifiers, regulator circuits, and transmitting transformers for both directions of transmission. Screwdriver-operated controls for the regulator and slope adjust network appear on the face of the unit. Also on the face is a 11-pin test socket which contains the following bridging test points:

1. The two amplifier outputs.
2. $B+$ and $B-$ leads.
3. The 304-kc oscillator output.
4. The cathodes of the two vacuum tubes.

The repeater unit plugs in and latches to the line-equipment unit or the mounting adapter.

The line-equipment unit contains the receiving span pads and line transformers and a voltage-dropping rheostat and resistor. The overvoltage protector circuit mounts in this unit when required. Space is provided to mount artificial lines and transmitting span pads when these are needed.

The line-equipment unit will contain the span pads and artificial lines which are peculiar to a particular location. Therefore, it is mounted as a semipermanent unit rather than as a latch-in unit. The line-equipment unit is attached to the shelf by two screws at the front of the unit.

Since the outside cable pairs are wired directly to the line-equipment unit, the space at the side of the shelf normally used for a shelf terminal block is available for an additional repeater. Five repeaters and their associated line-equipment units will mount on a single shelf on a 19-inch rack and will occupy only $12\frac{1}{4}$ inches of vertical space. Fig. 18 shows nine *45BN* repeaters installed in a pole-mount cabinet.

When the *45BN* repeater is used on Western Electric type *N* repeater shelves, a mounting adapter is available to take the place of the line-equipment unit. Fig. 19 shows the repeater unit plugged into the adapter. The adapter contains the same circuitry as the line-equipment unit except for circuits which are normally mounted on the *N* repeater shelf itself. The *45BN* repeater in the mounting adapter is mechanically and electrically interchangeable with Western Electric type *N* repeaters on Western Electric rack assemblies.

Conclusions

A new repeater has been developed for cable carrier use. The new repeater takes advantage of the frequency-frogging technique to achieve low-gain requirements and a minimum of external equalization. Transistors have been used extensively to reduce the size and power requirements. The low power requirements, in turn, permit tandem power feed to remote repeaters over the cable pairs. The need for many expensive power sources is thereby eliminated. Although designed primarily for the Lenkurt *45BN* systems, the new repeater will work equally well with Western Electric types *N* and *ON* systems.

Failure-Rate Studies on Silicon Rectifiers

N. F. BECHTOLD
ASSOCIATE MEMBER AIEE

C. L. HANKS
NONMEMBER AIEE

THE magic word semiconductor has been placed upon the lips of almost every electronically minded individual in the United States through untiring publicity efforts by manufacturers and their representatives. In accomplishing this purpose, the sales promoter often has impaired the future value of these new devices with predictions of unlimited life and hopeful claims for operating capabilities. These claims, although corroborated by theory, apparently have not yet been fulfilled in reasonable quantity with present production techniques for low-power silicon rectifiers. Until greater reproducibility can be attained, derating of both forward current and reverse voltage is necessary for a useful low failure rate.

The data reported herein are the result of only one of many evaluation programs being carried out by the military to determine the suitability of these varied semiconductor devices for the stringent operating environments encountered in tactical military applications. Operating life capabilities of low-power silicon rectifiers are discussed to acquaint systems application engineers with the unexpectedly high failure rates and related reliability factors demonstrated in an evaluation program begun about 18 months ago, and conducted jointly by the U. S. Army Signal Engineering Laboratories and the Battelle Memorial Institute.

Test Program

SAMPLES

Rectifiers used in this evaluation were in the lower power rating range, i.e., less than 500 ma (milliamperes). Their voltage ratings were also low when compared with the ratings of some silicon rectifiers now available, since no rectifier tested was rated at more than 400 PIV (peak inverse volts) nor less than 100 PIV. Rectifiers of higher power ratings were not included because they were still considered to be in the development stage at the outset of this program.

Five manufacturers were represented, and samples tested included both lead- and stud-mounted types of the "top hat" variety. To reduce the variables of extraneous heat-dissipation surfaces during test, the rectifiers were suspended on nonconducting glass filaments. A minimum of 5 inches separated the test samples from each other and from any object that could provide a heat sink. This method of mounting was chosen to eliminate the additional variable introduced by the better dissipation properties of the stud-mounted units.

Differences in forward current rating for the same over-all package size necessitated an operating scheme whereby all types, regardless of manufacturer, would be operated under equal failure-stimulating conditions. Since the least common denominator of all the samples was a silicon junction, a maximum safe operating junction-temperature range of about 150 to 180 C (degrees centigrade) was chosen as a starting point. Average junction temperature is difficult to ascertain, so case temperature was chosen as the next alternative, recognizing that some minor differences in internal package design could result in some inequalities in heat-dissipation properties. These

design differences can be attributed to either thickness and surface area of the silicon wafer, or fabrication of the junction proper. With regard to the latter technique, some manufacturers use the circular area of a wire butted against the silicon surface, while others achieve a larger junction area by using a greater portion of the silicon wafer cross section.

Test Procedure

Initial tests to determine the output current required to produce a desired temperature rise at the base of the rectifiers were performed on several units of each type and manufacture. The results shown in Table I are the approximate averages of the currents required. The 40 C rise test was specifically designed to stimulate failure, since it was recognized that forward currents in excess of manufacturers' ratings, necessary to achieve this condition, would contribute to significant junction heat rise. The data gathered for these conditions were used merely as a basis for study of failure mechanisms, and not considered as part of an over-all quality evaluation. The 20 C temperature rise, however, required that test samples be operated at or near the manufacturer's specification, thereby simulating normal-rated operation. Each initial sampling test established an operating current for each manufacturer's product in a subsequent related load-life test.

Three load-life tests were conducted during this program as follows: 1. an initial case-temperature rise of 40 C at the base of the rectifiers in an ambient temperature of 100 C, 2. an initial case-temperature rise of 40 C in an ambient temperature of 25 C, and 3. an initial case-temperature rise of 20 C in an ambient temperature 100 C. With one exception, groups of all the rectifier types and manufacture in a particular test were operated at their rated voltage. To study the effect on failure rate of reverse voltage alone, groups of the low-current higher-voltage (400 volts) types of manufacturers *BU*, *BV*, and *BW* were operated with resistive-capacitive loads at 75% of their rated voltage in the 25 C and 100 C ambient load-life tests with a 40 C initial case-temperature rise.

Load was applied continuously to the rectifiers during these tests, and measurements made with a dynamic analyzer. Fig. 1 is a circuit diagram of this test unit. The circuit employs three blocking diodes which enable the operator to measure the alternating voltage applied, output voltage, output current, dynamic forward voltage drop, and dynamic reverse leakage current simultaneously, without interruption of load. In addition, thermocouples attached to each individual recti-

400−*RC*..	rated at 400 PIV, operated into resistive-capacitive load
a/*b*.......	*a* is the load current value at which a unit is operated for a specific condition, and *b* is rated load current of that unit as specified by the manufacturer

Example: *BU* (400/200), (100+40) means the 200-ma rated item from manufacturer *BU* was operated at 400 ma to generate a 40 C case-temperature rise in a 100 C ambient.

Discussion of Results

PRELIMINARY EVALUATION

As indicated in the foregoing reference to Table I, preliminary tests were run on small sample sizes in order to establish basic operating conditions for load-life tests. At this early stage, these samples were assumed to be representative of the larger batches to follow. Minor variations of ±5 C were, at the time, satisfactory justification for establishing the test points.

Initial characteristic tests performed thereafter on the main body of samples gave indication that the foregoing reasoning was fallacious. Fig. 2 demonstrates the initial tolerances exhibited in the products of one manufacturer; for any test performed close to a critical operating point, it is apparent that there would be many deviations from an operating temperature established as an average from a small sample. Since forward power losses initially contributed to more than 90% of the total dissipation, it is evident that small variations in forward voltage drop can result in very significant differences in current necessary to attain a specified case temperature. In this regard, the item having an extremely low forward drop can be greatly penalized by a necessary high current density which, although resulting in required case temperature, has provoked a junction hot-spot temperature beyond the safe limit. (As is shown later, variations between reverse characteristics also become significant after some aging has taken place.)

Consider, for instance, samples from manufacturer *BU*, rated basically at 400 ma and 200 ma, as illustrated in Fig. 3. The 100-PIV versions of this series required 500 and 400 ma, respectively, to

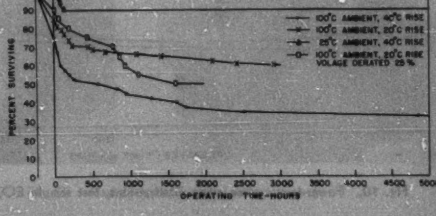

Fig. 8. Survival of high-PIV silicon rectifiers

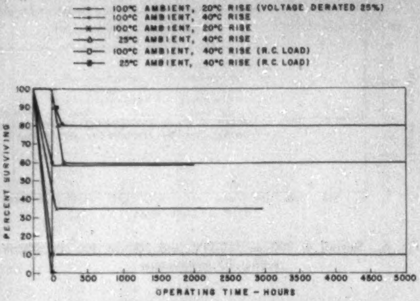

Fig. 9. Survival of high-PIV silicon rectifiers, BV manufacturer

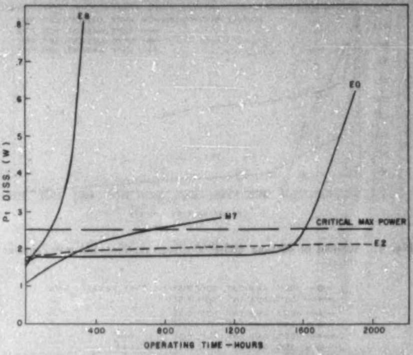

Fig. 11. Power-dissipation aging characteristics

effect a 40 C case-temperature rise. Were the higher current item of comparable quality with the lower current version, it would have required twice the power, therefore, approximately twice the forward current to bring the case to the desired temperature. Only a 25% greater forward current and a 50% greater forward current were necessary to bring the 400-ma unit to case-temperature rises of 40 C and 20 C respectively as shown in Table I. Even these differences are easily explained, since reverse current increases and contributes more to heating with increased forward currents and junction temperatures. Were the 400-ma curve to fall near the dashed line of Fig. 3, the desired result would be achieved since each would generate equal power at its respective rated value. It is readily apparent from the foregoing discussion that the manufacturer, in decreasing production costs, has tended to sacrifice reliability in the higher current items.

LOAD-LIFE TESTS

Figs. 4 and 5 give an immediate indication of the relative reliability of the two types discussed in the foregoing. Suggestions are made later for possible failure-rate improvement of the 200-ma type, but the 400-ma version is apparently below even the lowest military quality standards in the 100 C ambient operating range. Note from Fig. 5 that no failures were noted under the (25+40) condition *R* load, whereas 10% failures resulted under *RC* load at the same test condition. On the basis of the small sample sizes of 10 or 20 available, this alone is not significant. However, these comparative results were experienced throughout the program for *RC*-loaded units operated at the same forward currents as *R*-loaded types. The manufacturer's recommended 20% derating for *RC* load appears adequate in the light of these results.

In view of excessive failures of higher voltage (400 PIV) units during the first 1,000 hours, it was decided to study the effect on failure rate of reverse voltage alone. Consequently, another test run was initiated at the (100+20) condition, with reverse voltage derated to 75%. Fig. 4 demonstrates an apparent advantage gained from this approach but reference to Fig. 5 apparently indicates a decrease in quality. These inconsistencies are a result of small sample size, and further tests must be run on larger sample sizes to determine the relative effects of various voltage-derating factors. Fig. 6, representing the comparative survival rates of low- and high-PIV items of manufacturer *BY*, indicates clearly the differences in quality at the particular test condition. Figs. 7 and 8 demonstrate load-life results of the two categories (100−*R*) and (400−*R*) respectively. The curves of Figs. 7 for (100−*R*) denote the closest approximation to desired military quality, especially for the (100+20) condition, which indicates a failure rate of less than 1% per 1,000 hours. Derating currentwise of even this series of items would be necessary to decrease this failure rate to a reasonable figure in the neighborhood of 0.1% per 1,000 hours.

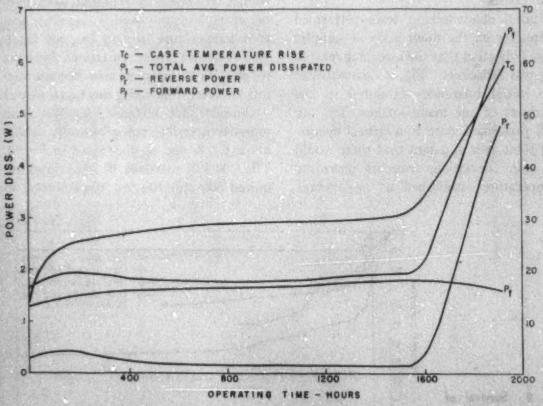

Fig. 10. Power-temperature aging relationships, test sample EO, BU manufacturer

Vol.
Pt. 1
1958

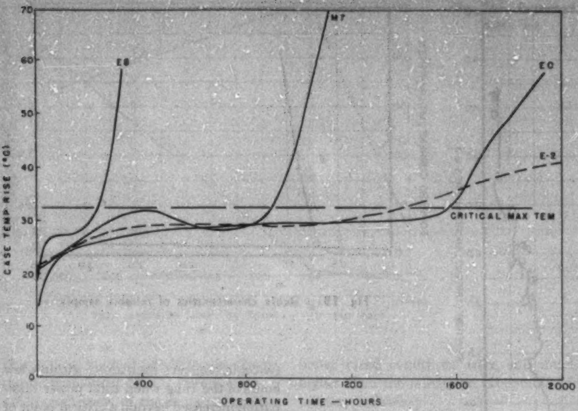

Fig. 12. Case-temperature aging characteristics

Fig. 8, representing high-PIV units, indicates failure rates well beyond any reasonable quality for military application at the rated condition of (100+20), and also at the accelerated condition of (25+40). It appeared throughout this program that the 400-volt items were more affected by high ambient temperature rather than by operating currents in excess of rated values.

Each of the foregoing discussed survival curves (and therefore failure-rate curves) approximated a decreasing exponential function of $y=e^{-as}$, or a constant "hazard" rate (per-cent failure of remaining samples), resulting in an early high per cent of failure which decreases with time. This effect is accentuated in Fig. 9, which indicates no failures for manufacturer *BV* samples beyond an initial burn-out period of about 200 hours. At an increase in unit cost, the manufacturer could weed out these undesirables with a 1-week factory test prior to shipment. Consider the effects of such a burn-out period from Figs. 7 and 8 and it is evident that the advantage gained would be significant in almost every case.

Table II. Modes of Failure

Effect	Cause
Overheating	overload, high ambient, poor dissipation
Junction breakdown	high reverse voltage
Loss of seal	poor quality control
Microphonics	loose elements—initial or after vibration
Insulation failure	moisture absorption, high potentials, poor basic design

NATURE OF FAILURES

Based upon the geometry of the device package, the heat generated at the junction is dissipated through thermal resistances of the junction, internal mounting members, and case. As previously stated, no external heat-dissipation surfaces were considered. Consequently, relatively high thermal resistance of the small devices (exceeding 0.1 C per megawatt) resulted in average junction temperatures higher than case temperature, hot spots considerably higher than this, and a purposely induced high failure rate for study.

The operating characteristics discussed here are all dependent upon the basic time-temperature relationships between power generated and heat dissipated. However, they are further complicated by the contributions of both forward and reverse power; see equation 1.

$$P_t=P_f+P_r=\frac{1}{(t_2-t_1)_f}\int_{t_1}^{t_2} e_f i_f dt+\frac{1}{(t_2-t_1)_r}\int_{t_1}^{t_2} e_r i_r dt \quad (1)$$

where

$(t_2-t_1)_f$ = period of flow of forward current
$(t_2-t_1)_r$ = period of flow of reverse current

In view of the nonlinear forward and reverse characteristics of a semiconductor rectifier, a complete mathematical treatment of these power relationships is beyond the scope of this paper. If, however, rectified half sine waves are assumed for the functions e_f, i_f, e_r, i_r, a simple calculation results in average power relationships of

$$P_f=\frac{E_{Mf}I_{Mf}}{2} \text{ or } \left(\frac{E_{Mf}}{\sqrt{2}}\right)\left(\frac{I_{Mf}}{\sqrt{2}}\right) \quad (2)$$

$$P_r=\frac{E_{Mr}I_{Mr}}{2} \text{ or } \left(\frac{E_{Mr}}{\sqrt{2}}\right)\left(\frac{I_{Mr}}{\sqrt{2}}\right) \quad (3)$$

where

E_{Mf} = peak value of forward voltage drop
I_{Mf} = peak value of load current
E_{Mr} = peak value of input voltage
I_{Mr} = peak value of reverse leakage current

Equations 2 and 3 signify that average power for each half-cycle is merely the rms products of voltage and current present during that half-cycle. These relationships were used to approximate magnitudes for the following discussion.

The actual contributions of both P_f

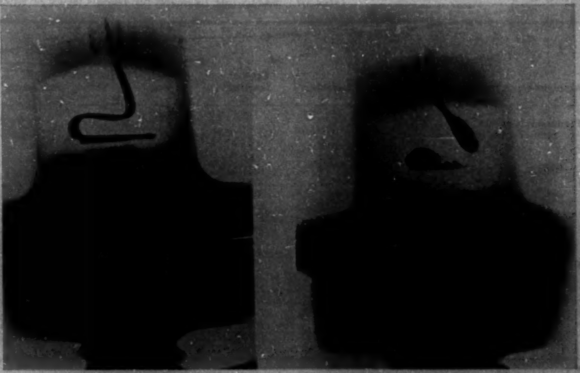

Fig. 13. Radiographs of typical failures

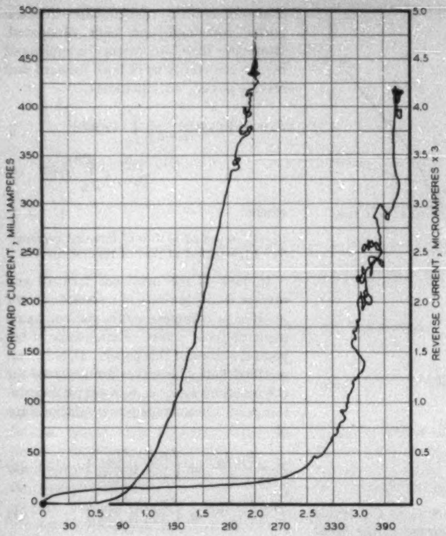

Fig. 14 (left). Forward and reverse instability

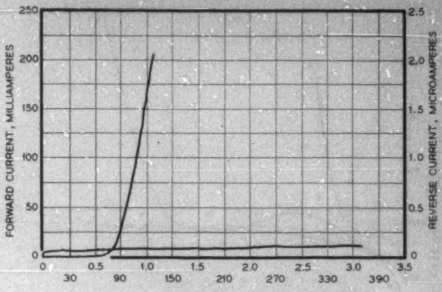

Fig. 15. Stable characteristics of reliable sample

and P_r to ultimate failure are illustrated in Fig. 10, where unit *E0* has been chosen as a typical example. The power dissipated due to forward losses remains essentially constant, at approximately 90% of the total losses, throughout the 1,500-hour useful life of the sample. Almost simultaneous runaway of reverse power, total power, and case temperature occur beyond this point. Forward and reverse power losses contribute equally at about 1,700 hours under this particular test condition. Figs. 11 and 12 further illustrate this temperature-power relationship for three other samples in addition to unit *E0*. *E8* and *M7* were early failures, while *E2* was still operating satisfactorily after 2,500 hours. It is especially significant that *E0*, *E8*, and *M7* reached a critical case-temperature rise of about 33 C (without recovery thereafter) within a few hours of the time when total power dissipation increased beyond a critical point of about 250 megawatts, thereby automatically limiting this series to about 400 ma d-c with negligible reverse losses. Further, with regard to Fig. 12, case temperature apparently rises rapidly during a 100-hour break-in period, then levels off for a period of time determined by end quality of the individual sample. At the point of permanent change, a high irreversible rate of temperature increase (in excess of 10 C per 100 hours) takes place to precede thermal runaway. Unit *E2*, however, did not experience these effects during the test period, and has provided satisfactory operation for at least 2,500 hours. Apparently some deterioration has taken place in *E2*, as evidenced by increase in case temperature beyond 33 C.

Table III. Mean-Life Estimates for Three Classes of Silicon Rectifiers

Ambient Conditions	Class of Rectifier	Type of Loading	Duration of Test, Hours	Reliability Data: Sample Size	Reliability Data: Successes	Reliability Data: Failures	Mean Life, Hours: Average Estimate	Mean Life, Hours: 95% Lower Confidence Limit	Approximate Failure Rate Per 1,000 Hours, Per Cent

‡ Resistive-capacitive load.

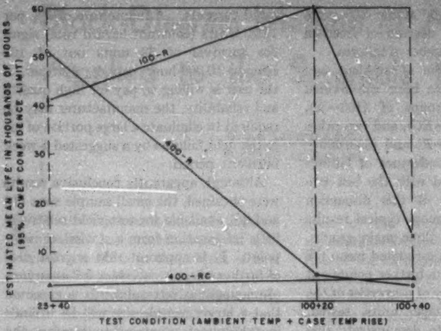

Fig. 16. **Estimated mean life**

This was a gradual gradient, however, and no permanent defects were noted.

Although some of the units under discussion were tested under accelerated operating conditions, the trends and overall results are indicative of, but more pronounced than, normal operation. However, the failure rates experienced under rated conditions were still much higher than the maximum acceptable for military reliability.

It is logical to conclude from the foregoing analysis that silicon rectifiers of the low-power types studied give prior warning of ultimate failure through a measureable high rate of change of case-temperature rise and power dissipation. Ultimate failure and subsequent lack of equipment reliability can therefore be avoided by close monitoring of diode characteristics, and replacement within 100 hours of any items having exceeded the critical points specified. A more practical alternative to the extension of equipment reliability is to provide sufficient derating of forward and reverse operating parameters, so as to extend these points of failure and to eliminate this need for component monitoring during equipment operation. Specific derating parameters are discussed later.

MECHANISMS OF FAILURE

For the purposes of this discussion, "end of life" is defined as that point where either the rectifier ceases operation catastrophically or thermal runaway is taking place. A maximum reverse leakage of 125 ma was chosen as the criterion for the latter condition.

Although test samples were essentially of equal mechanical and physical construction, failures noted were of both the

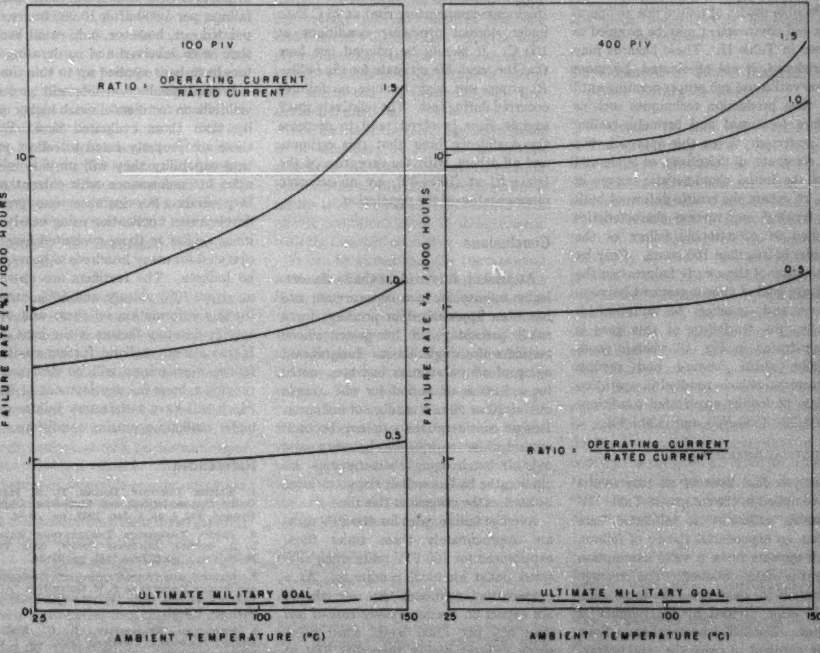

Fig. 17. **Proposed failure rate curves, low-power silicon rectifiers**

open- and short-circuit variety. The open-circuit-type failure was unique in that it only occurred with rectifiers of manufacture *BU*. This type of failure occurred in all three load-life evaluations and was generally preceded by an increasing forward voltage drop and temperature rise at the base of the rectifier. The reverse leakage current varied generally, with increases to several milliamperes in a few cases. Radiographs of two rectifiers that suffered this type of failure are shown in Fig. 13. Rectifier *A* of this figure has a separation at the alloyed area between the silicon wafer and the aluminum wire. Internal arcing has resulted in the melting of the aluminum wire in rectifier *B*. The failure-by-short-circuit effect was general in the higher PIV rectifiers of all the manufacturers. This type of failure follows a gradually increasing reverse leakage current that sometimes reaches several milliamperes, which then increases to a value greater than 125 ma or approaches a direct short circuit (thermal runaway). Actual short-circuiting was confined to rectifiers on resistive-capacitive load in the (100+40 C) and (25+40 C) load-life evaluations.

Possible modes of failure due to operation and environment may be grouped as shown in Table II. These hazards may be reduced, if not eliminated, by more conservative use and proper derating until the time production techniques such as surface treatment and hermetic sealing are perfected. Even this approach will not eliminate all defectives, as evidenced from the initial characteristic curves in Fig. 14, where the erratic nature of both the forward and reverse characteristics resulted in catastrophic failure of the rectifier in less than 100 hours. Only by elimination of these early failures can the ultimate goal of close agreement between theory and practice be approached. Ideally, the feasibility of this goal is demonstrated in Fig. 15, wherein good, initially stable, forward and reverse characteristics have resulted in operation to date under the accelerated conditions of 500/200, (350-*RC*), and (100+40).

STATISTICAL ANALYSIS

Analysis had been of all test results and compiled in the composite Table III. Mean-life estimates as tabulated here assume an exponential theory of failure, which appears to be a valid assumption from the data obtained. The average estimate is the quotient of the total hours of operation divided by the number of failures. The 95% lower confidence limit is the quotient of twice the total operating hours divided by χ^2 at the 0.05 probability level with degrees of freedom equal to twice the number of failures.

Each test condition of ambient and case temperature has been sub-divided into three main groups of (100−*R*), (400−*R*), and (400−*RC*), and two other groups of (350/400−*R*) and (350/400−*RC*). Since a preponderance of failures has been experienced with the last two categories, the rest of this discussion relates only to the more typical results noted for the other three main groups. A consistently longer estimated mean life for the (100−R) units further points out the relative inequality of properties of the low- and high-voltage units tested. Fig. 16 may tend to demonstrate this point. (Statistically, it is incorrect to connect the points into a continuous function, since different sample size and test periods were involved at each temperature condition. This approach was taken only for the purposes of text clarification.) Note especially how the 400-volt units, under both loading conditions, suffered greatly at the higher ambient temperatures, while the 100-volt items were more adversely affected by high current density (high case-temperature rise) at 25 C than under normal operating conditions at 100 C. It should be pointed out here that the mean-life estimate for the (400−*R*) group was high because no failures occurred during test. The relatively small sample sizes involved tend to decrease the confidence limit that this estimate and all others, with the exception of the (100−*R*) at (100+20), are an accurate representation of the population.

Conclusions

At present, it is evident that a theoretically infinite life can be expected, and has been approached in practice, for a small percentage of low-power silicon rectifiers of a single batch. Insignificant aging of all parameters has been noted for a 5,000-hour period for one sample out of 10 or 20 in a number of instances. Design considerations can not be built around these exceptions, however, and over-all batch aging characteristics, including the bad as well as the good, must be used as the criteria at this time.

Average failure rates for 400-PIV units are approximately three times those experienced for 100-PIV units when analyzed under identical conditions. As a conservative estimate, the user should not expect an average failure rate of less than 5% per 1,000 hours when using single cells at higher than 200 PIV at rated currents. A failure rate of 5% per 1,000 hours (constant hazard rate) signifies survival of 62 units out of 100 after a 10,000-hour period. Further, if the user is willing to pay for high quality and reliability, the manufacturer may be required to eliminate a large portion of his initial field failures by a suggested 1-week burn-out period.

Although apparently conclusive results were obtained, the small sample sizes (10 and 20) available for test yield relatively little information from a statistical viewpoint. It is apparent that a great deal of further effort is necessary for assurance of unquestionable results. It is expected that a larger sample size will be utilized in subsequent programs to increase the level of confidence and provide sufficient information to complete the curves noted in Fig. 17. Three points on each set of curves have already been approximated from the test results to date and may serve as a guide toward conservative design and application. A 100-PIV unit at rated current, for example, when operated in a 100 C ambient, will yield almost seven failures per 1,000 in the first 1,000 hours, and more than 60 failures per 1,000 after 10,000 hours. As pointed out, however, only small sample sizes were involved and no derating factors have been applied up to this time.

Present production lots will probably yield silicon rectifiers of much higher quality than those evaluated here. When these are properly rated to reflect practical capability they will provide failure more in conformance with current military needs. For instance, one present development application using nearly 100 items similar to those evaluated here has operated for many hundreds of hours with no failures. The rectifiers are operated at about 70% voltage and 50% current. Further information on these and other specific derating factors is the next goal. If they are not realistic, further studies of failure mechanisms will be designed to provide a basis for development of items which will have satisfactory failure rates under realistic operating conditions.

Block-Diagram Method of Analysis Applied to the Saturable Reactor

R. M. HUBBARD
ASSOCIATE MEMBER AIEE

THE saturable-reactor class of magnetic amplifiers has recently received considerable attention as the subject of new analyses efforts.[1,2] Although the saturable reactor antedates the self-saturating class of magnetic amplifiers, it is by no means functionally simpler and does not afford the easiest starting point for a general analysis of magnetic amplifiers. Therefore, in a previous paper,[3] the author introduced a block-diagram method of analysis as applied to the self-saturating class of magnetic amplifiers. It was shown that both half-cycle response circuits and conventional full-wave circuits can be analyzed by a single theory and that, in fact, the two differ only by the amount of feedback present. As an extension of the block-diagram method of analysis to the saturable reactor, this paper is intended to lend further support to the premise that all classes of magnetic amplifiers are basically of the same genus and therefore should be describable by a single theory. The use of the block diagram is particularly effective in clarifying the relationship between the saturable-reactor class and the self-saturating class of magnetic amplifiers.

Philosophy of Saturable-Reactor Analysis

The basic mode of operation of saturable reactors is such that, for purposes of a general transfer function, consideration of increments of time smaller than one half-cycle of the carrier frequency is meaningless. The operation of saturable reactors can, however, be described in terms of half-cycle average values. Although analyses based on instantaneous values provide a valuable insight into the mechanics of saturable-reactor operation, the details of the various operating modes tend to detract from a clear understanding of the basic nature of the device.

The simplicity of the following analysis is dependent on the fact that saturable-reactor operation can be examined over discrete (half-cycle) increments of time if any commutation effects are negligible. Therefore, it is assumed that the load current goes to zero at the end of each half-cycle of the carrier frequency. This assumption effectively restricts the operation of the saturable reactor to a single mode and, in fact, is substantially the same assumption previously used to simplify the analysis of the self-saturating class of amplifiers. Fortunately, the resultant general conclusions which are reached with the help of this assumed condition are not invalidated by its absence. Several operating conditions inherently satisfy the requirements of this assumption. For example, the parallel saturable reactor always operates in the assumed manner. In addition, in the case of the series saturable reactor, the use of a square-wave supply voltage or a rectified a-c control voltage with a sinusoidal supply voltage normally assures that the load current will go to zero when the supply voltage changes sign. Clearly, highly inductive loads produce a type of operation which can not be handled by this method of analysis.

The fact that the foregoing assumption is of secondary importance is further evidenced by the excellent correlation between the theory and the experimental results (Fig. 17) which were obtained with circuit conditions often in disagreement with the assumed condition.

It can be shown that the conventional methods of circuit analysis (Kirchhoff's laws, etc.) apply to the analysis of magnetic-amplifier circuits when all voltages are expressed in terms of half-cycle average values as well as when all voltages are expressed in terms of instantaneous values. The use of half-cycle average values, however, has the advantage that no consideration need be given to the various changes of state resulting from core saturation. Therefore, the only necessary equivalent circuit is merely the original circuit diagram with all voltages expressed as average values

Nomenclature

A = amplification factor
A_i = intrinsic amplification factor due to core characteristic
A_i' = intrinsic amplification factor due to coupling between reset and load circuits
A_o = generalized amplification factor
$\bar{e}_c$ = half-cycle average control voltage
$\bar{E}_c$ = average steady-state control voltage
$\bar{e}_g$ = half-cycle average gate voltage across load winding
$\bar{e}_g'$ = half-cycle average gate voltage referred to control winding
$\bar{e}_L$ = half-cycle average load voltage (across R_L)
$\bar{e}_o$ = half-cycle average output voltage
$\bar{E}_o$ = average steady-state output voltage
$\bar{e}_r$ = half-cycle average reset voltage across load winding
$\bar{e}_r'$ = half-cycle average reset voltage referred to control winding
$\bar{E}_s$ = average rectified supply voltage
$G(s)$ = frequency variant portion of transfer function $KG(s)$
$\bar{I}_c$ = half-cycle average current in control winding
K = static voltage gain associated with transfer function $KG(s)$
N_c = number of turns in control winding
N_x = number of turns in load winding
$\bar{R}$ = average excitation impedance of saturable transformer referred to the load winding
R_c = total series resistance in control circuit
r_c = resistance of control (N_c) windings
R_L = load resistance
R_r = leakage resistance of the rectifier
r_x = resistance of load winding plus the forward resistance of the rectifier
s = complex frequency variable
T = time for one half-cycle of supply (ω_c)
τ_a = amplifier 63% response time
ω_c = supply frequency in radians per second
ω_0 = "break frequency" or frequency for 45-degree phase shift

Development of Block Diagram for Series Saturable Reactor

Reference to the series saturable-reactor circuit diagram of Fig. 1(A) permits a simple introduction to the block-diagram type of analysis. The two component saturable transformers T_1 and T_2 are represented in equivalent-circuit form in accordance with the technique previously applied to the self-saturating circuits.[3] Thus, the nonlinear excitation impedance is represented by an average resistance $\bar{R}$ and the resistance of each load winding is lumped into the total series load-winding resistance r_x. Likewise the resistance of each control winding is lumped into the total series resistance of the control circuit R_c. It should be noted that the representation of the nonlinear magnetic characteristics of the core by the parameter $\bar{R}$ is not an attempt to linearize this quantity. By including this one nonlinear factor in the block diagram without specifically evaluating

A—Circuit diagram

B—Block diagram

it, important general conclusions can be easily reached. The evaluation of $\bar{R}$ is rightfully the subject of a separate investigation such as the very excellent work recently described by Kikuchi and Feth.[4,5]

For a given saturable transformer, the net flux change over a complete cycle of resetting and subsequent gating must be zero. In addition, the application of the previously mentioned assumption effectively assures a symmetrical type of operation such that the magnitudes of the flux changes over the two equal half-cycle increments of time are equal. Therefore, the magnitude of the volt-time integral absorbed by the load winding N_x during the resetting half-cycle equals the magnitude of the volt-time integral absorbed by the same winding during the subsequent gating half-cycle. Thus, in the case of a given transformer, the magnitude of the average gate voltage in the nth half-cycle $\bar{e}_g(nT)$ equals the magnitude of the average reset voltage in the preceding $(n-1)$th half-cycle $\bar{e}_r(n-1)T$.

The following description of the operation of the series saturable reactor of Fig. 1(A), based on the block diagram of Fig. 1(B) and the transformed block diagram of Fig. 2, serves to illustrate the straightforward relationship between circuit diagram and block diagram. An analytical development of the block diagram is presented in Appendix I.

During the indicated half-cycle of the supply voltage, transformer T_1 is gating and transformer T_2 is resetting. The average reset voltage $\bar{e}_r'$ applied to the control winding of T_2 is the sum of three voltages. These are the signal voltage $\bar{e}_c$, the intrinsic delayed positive-feedback voltage $\bar{e}_g'$ produced by the series-connected control windings, and the intrinsic negative-feedback voltage $\bar{i}_cR_c$. This last voltage is due to the summation of the IR drops produced by core excitation current (dictated by the excitation impedance $\bar{R}$) and, in the simplified block diagram (Fig. 2), the transformer-coupled load current $\bar{i}_L$. The reset voltage referred to the load circuit $\bar{e}_r$ in the given half-cycle is equal to the gate voltage $\bar{e}_g$ effective in the subsequent half-cycle; thus the half-cycle time delay ϵ^{-Ts} is introduced using Laplace notation. The average output voltage $\bar{e}_o$ is the difference between the average supply voltage E_s and the sum of the gate voltage $\bar{e}_g$ and the reset voltage $\bar{e}_r$. The load current $\bar{i}_L$ is the ratio of output voltage to the total resistance in the load circuit (R_L+r_x), and the load voltage, of course, is the product of the load current $\bar{i}_L$ and the load resistance R_L.

A steady state is achieved when the gating voltage in one half-cycle equals the gating voltage in the subsequent half-cycle. Therefore, in a given half-cycle under steady-state conditions, the gating voltage $\bar{e}_g'$ must equal the reset voltage

$\bar{e}_r'$. From the block diagram it can be seen that a necessary condition for a steady state is that the sum of the signal voltage $\bar{e}_c$ and the intrinsic negative-feedback voltage $\bar{i}_c R_c$ be zero. This is, of course, exactly what one expects. The symmetrical nature of the circuit makes the block diagram valid for both half-cycles of the supply voltage.

Observations Based on Block Diagram

Although the block diagram of Fig. 2 affords a simpler introduction to this technique, the block diagram of Fig. 1(B) is the more generally useful form. Thus, the average reset voltage $\bar{e}_r'$ across the control winding is determined by the ratio of the impedance presented by that winding to the external resistance in the control circuit R_c. In the self-saturating circuit (Fig. 8) this impedance ratio is simply the ratio of reflected excitation impedance to control-circuit resistance, i.e., $A_i = \hat{R}(N_c/N_x)^2/R_c$. However, in the case of the saturable reactor, the decoupling action provided by self-saturating rectifiers is absent. As a result, the impedance presented by the control winding is the parallel combination of the reflected excitation impedance $\hat{R}(N_c/N_x)^2$ and the reflected load-circuit resistance $(R_L+r_x)(N_c/N_x)^2$, modified by the delayed negative-feedback effect of the gate voltage (via the lower feedback loop). Unlike the self-saturating circuit, two intrinsic amplification factors must be defined; namely, $A_i = \hat{R}(N_c/N_x)^2/R_c$ and $A_i' = (R_L+r_x)(N_c/N_x)^2/R_c$.

It is of interest to note that the time constant normally associated with saturable reactors does not appear in the proposed block diagrams. It will be shown that this familiar lag is a direct result of the intrinsic positive-voltage feedback produced by the series-connected control windings. This particular feedback loop is shown on the block diagram as the gate voltage $\bar{e}_g$ fed back through the turns ratio N_c/N_x into the control-circuit summing point.

One interesting distinction between the self-saturating class and the saturable-reactor class of magnetic amplifiers is clearly illustrated by the block diagram. In the case of the latter class, there is a forward transmission path which bypasses the delay ϵ^{-T_s} and contributes directly to the output. Thus, although a minimum response time of one half-cycle is inevitable in the case of the self-saturating amplifier, there is no such limit on the speed of response of the saturable reactor. The common assumption that the response of the saturable reactor to a step-function input may be represented, for relatively slow response amplifiers, as a pure delay and single time constant will be shown to be incompatible with the transfer function which derives from the block diagram. It will be seen subsequently that, as a result of the foregoing distinction, the gain-bandwidth product of the series saturable reactor is twice that of the self-saturating magnetic amplifier.

Parallel Saturable Reactor

The techniques developed for the series saturable reactor may also be applied to the parallel saturable reactor of Fig. 3(A) to yield the block diagram of Fig. 3(B). The similarity between the two types is more clearly illustrated by a comparison of their block diagrams than by a comparison of their circuit diagrams.

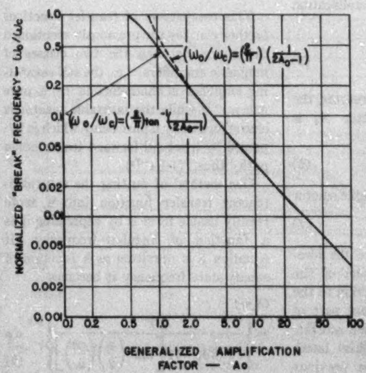

Fig. 5 (left). Normalized break frequency versus the generalized amplification factor A_0

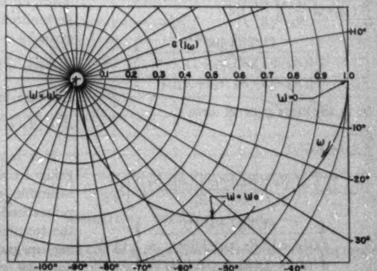

Fig. 6 (right). Polar co-ordinate plot of G(jω) for the saturable reactor

Most of the observations based on the block diagram of the series saturable reactor also apply to the parallel saturable reactor. However, there is one interesting distinction. Note that the delayed feedback introduced by the lower feedback loop of Fig. 3(B) is positive feedback, while in the series circuit the corresponding loop introduced negative feedback. It will be seen that this positive feedback raises the gain above what would normally be a very low value due to the fact that the impedance of the resetting control winding is shunted by the normally small reflected winding resistance r_x. This positive-feedback loop also serves to make the response time of the parallel saturable reactor considerably greater than that of the equivalent series saturable reactor.

Saturable-Reactor Transfer Functions

In a properly designed saturable reactor, the excitation impedance of the core is negligibly high compared with the load resistance, therefore, the intrinsic feedback loop involving this factor is omitted, i.e., $A_f \to \infty$, in the derivation of the transfer functions from the block diagrams.

The transfer function for the series saturable reactor may be written directly from the block diagram, for incremental quantities, as

$$\frac{\bar{e}_L}{\bar{e}_c}(s)=\left(\frac{N_c}{N_x}\right)\left(\frac{R_L}{R_c}\right)\left|\frac{1+\epsilon^{-Ts}}{(A_t'+1)-(A_t'-1)\epsilon^{-Ts}}\right| \qquad (1)$$

or in the more general form,

$$\frac{\bar{e}_o}{\bar{e}_c}(s)=KG(s)=\left[\left(\frac{N_x}{N_c}\right)(A_t')\right]\times \left[\frac{1+\epsilon^{-Ts}}{(A_t'+1)-(A_t'-1)\epsilon^{-Ts}}\right] \qquad (2)$$

In like manner, the transfer function for the parallel saturable reactor may be written from the block diagram of Fig. 3(B) as

$$\frac{\bar{e}_L}{\bar{e}_c}(s)=2\left(\frac{N_c}{N_x}\right)\left(\frac{R_L}{R_c}\right)\times \left\{\frac{(1/2)(1+\epsilon^{-Ts})}{[(A_t'+1)(R_L/r_x+1)]-[(A_t'+1)(R_L/r_x)+A_t']\epsilon^{-Ts}}\right\} \qquad (3)$$

or, in the more general form

$$\frac{\bar{e}_o}{\bar{e}_c}(s)=KG(s) =\left[2\left(\frac{N_x}{N_c}\right)\frac{(R_L+r_x/2)(N_c/N_x)^2}{R_c}\right]\times \left\{\frac{(1/2)(1+\epsilon^{-Ts})}{(A_t'+1)(R_L/r_x+1)]-[(A_t'+1)(R_L/r_x)+A_t']\epsilon^{-Ts}}\right\} \qquad (4)$$

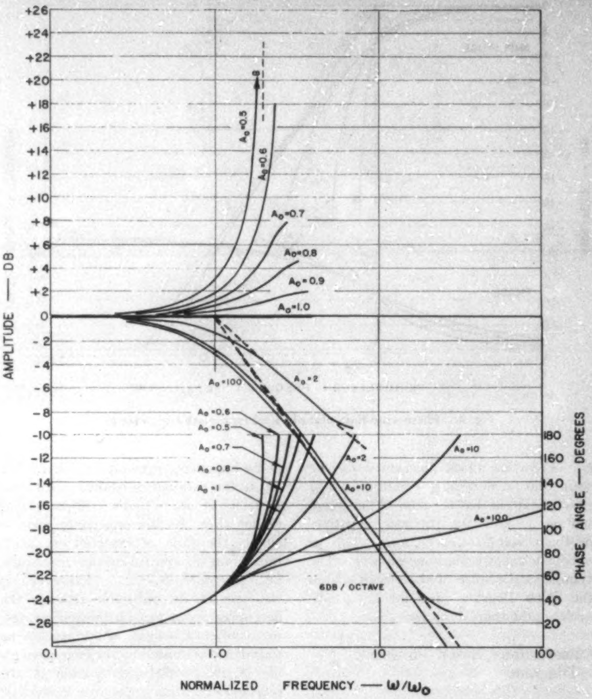

Fig. 7. Phase-amplitude plot of G(jω) for the self-saturating magnetic amplifier

It has been found that, in the interest of simplicity, the frequency-dependent part of the foregoing transfer functions can be reduced to the following general form, where A_o is the generalized amplification factor.

$$G(s)=\frac{1}{2}\left[\frac{(1+\epsilon^{-Ts})}{A_o-(A_o-1)\epsilon^{-Ts}}\right] \qquad (5)$$

Thus, for the series saturable reactor, the generalized amplification factor A_o is given by

$$A_o=(A_t'+1)/2 \qquad (6)$$

Likewise, for the parallel saturable reactor

$$A_o=(A_t'+1)(R_L/r_x+1) \qquad (7)$$

It is interesting to compare the foregoing frequency-dependent part of the saturable-reactor transfer function to the generalized frequency-dependent part of the transfer function for the self-saturating magnetic amplifier. This latter quantity, as taken from the previous paper,[8] is as follows:

$$G(s)=\left[\frac{\epsilon^{-Ts}}{(A_o)-(A_o-1)\epsilon^{-Ts}}\right],\quad A_o=(A_t+1) \qquad (8)$$

This comparison of transfer functions further clarifies the previously mentioned distinction between the two classes of magnetic amplifiers; i.e., the self-saturating amplifier is characterized by a pure delay ϵ^{-Ts} while the saturable reactor is characterized by a pure delay which is by-passed by a second forward transmission path, thus, $(1+\epsilon^{-Ts})$.

One method of putting the saturable-reactor transfer function into a more readily usable form is by expressing it as a function of angular frequency. If equation 5 is rewritten as a function of steady-state frequency it becomes

$$G(j\omega) =\left\{\frac{1}{1+(2A_o-1)^2\left[\tan^2\left(\frac{\pi}{2}\right)\left(\frac{\omega}{\omega_c}\right)\right]}\right\}^{1/2} <\phi \qquad (9)$$

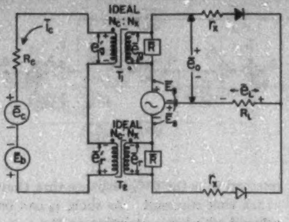

Fig. 8. Simple self-saturating (center-tapped) magnetic-amplifier circuit diagram

where

$$\phi = -\tan^{-1}\left[(2A_o-1)\tan\left(\frac{\pi}{2}\right)\left(\frac{\omega}{\omega_c}\right)\right] \tag{10}$$

and ω_c is the carrier (supply-voltage) angular frequency.

If ω_o is the frequency at which $\phi=45$ degrees, then

$$\frac{\omega_o}{\omega_c} = \left(\frac{2}{\pi}\right)\tan^{-1}\left(\frac{1}{2A_o-1}\right) \tag{11}$$

The substitution of equation 11 into equations 9 and 10 yields

$$G(j\omega) = \left\{\frac{1}{1+(2A_o-1)^2\tan^2\left[\left(\frac{\omega}{\omega_o}\right)\tan^{-1}\frac{1}{2A_o-1}\right]}\right\}^{1/2} < \phi \tag{12}$$

and

$$\phi = -\tan^{-1}(2A_o-1)\times \left\{\tan\left[\left(\frac{\omega}{\omega_o}\right)\tan^{-1}\frac{1}{2A_o-1}\right]\right\} \tag{13}$$

Equations 12 and 13 are plotted in Fig. 4, and equation 11 is plotted in Fig. 5. The phase-amplitude plot of Fig. 4 reveals some rather remarkable things about the saturable reactor. Clearly, in one limit ($A_o \rightarrow \infty$), the operation of the saturable reactor approaches that of a simple first-order system which is characterized by a single time constant. However, in the other limit ($A_o \rightarrow 0.5$), the operation is that of an ideal low-pass filter. The polar co-ordinate plot of $G(j\omega)$ which appears in Fig. 6 reveals the interesting fact that the relationship between amplitude and phase is that of a first-order system regardless of the value of A_o. Thus the attenuation is always 3 decibels when ϕ is 45 degrees, and the attenuation always approaches infinity as ϕ approaches 90 degrees.

A comparison of the foregoing phase-amplitude plot to that of the self-saturating magnetic amplifier, shown in Fig. 7 reveals the appreciable basic difference between the transfer functions of the two classes of magnetic amplifier. Obviously in one limit, i.e., $A_o \rightarrow \infty$, the operation of both devices approaches that of a simple first-order system which is characterized by a single time constant. However, as the operation departs from this limit, the self-saturating circuit exhibits less attenuation and more phase shift, while the saturable reactor is characterized, by both increased attenuation and increased phase shift (at frequencies higher than the break frequency ω_o). In the simple self-saturating circuit with no external feedback, shown in Fig. 8, as the circuit is forced toward fast re-

sponse by increasing the control-circuit resistance R_c, the operation approaches the limit in which the intrinsic amplification factor A_i approaches zero, and the generalized amplification factor A_o becomes equal to one. When A_o is equal to one, the operation corresponds to a pure delay, i.e., phase shift with no attenuation. In the case of the series saturable reactor the analogous situation causes the generalized amplification factor A_o to approach one half. Therefore it can be seen that, in the case of the latter circuit, the limiting operation for fast response corresponds to an ideal low-pass filter. Clearly, if the common assumption that the self-saturating circuit is characterized by a pure time delay and a single time constant is valid, then this same assumption can not properly be applied to the saturable reactor.

It is interesting to note that the application of external feedback to the self-saturating amplifier can cause A_o to be less than one and produce underdamped (oscillatory) operation. The limit of this operating region ($A_o=0.5$) is an unstable condition in which the amplitude goes to positive infinite at $\omega/\omega_o=2$. This condition is in marked contrast to the saturable reactor (at $A_o=0.5$), in which the amplitude goes to negative infinity.

Saturable-Reactor Response Time

If $A_o \geq 5$, the relationship between break frequency ω_o and the generalized amplification factor A_o can be expressed with good approximation (see Fig. 5) as

$$\frac{\omega_o}{\omega_c}=\left(\frac{2}{\pi}\right)\left(\frac{1}{2A_o-1}\right),\ A_o \geq 5 \tag{14}$$

A study of Fig. 4 reveals that a first-order approximation is valid for values of A_o greater than ten. Therefore, an equivalent time constant for the saturable-reactor response to a step function can be written as follows

$$\tau_a=\frac{1}{\omega_o}=\left(\frac{\pi}{\omega_c}\right)\left(\frac{2A_o-1}{2}\right),\ A_o \geq 10 \tag{15}$$

Further, if one lets $\pi/\omega_c=T$, the time for a half-cycle of the carrier voltage, then

$$\tau_a=\left(\frac{2A_o-1}{2}\right)(T),\ A_o \geq 10 \tag{16}$$

It is shown subsequently that τ_a is better referred to as the 63% response time than as the time constant. As such, τ_a can be utilized with less restriction on the value of A_o.

The expression for response time can be put into terms of the individual saturable-reactor parameters by utilizing equations 6 and 7. Thus, for the series saturable reactor

$$\tau_a=(A_i'/2)T=\frac{1}{2}\left(\frac{R_L+r_x}{R_c}\right)\left(\frac{N_c}{N_x}\right)^2\left(\frac{\pi}{\omega_c}\right),\quad A_o \geq 10 \tag{17}$$

or

$$\tau_a=\frac{1}{4f}\left(\frac{R_L+r_x}{R_c}\right)\left(\frac{N_c}{N_x}\right)^2,\ A_o \geq 10 \tag{18}$$

For the parallel saturable reactor

$$\tau_a=\frac{1}{2}\left[2(A_i'+1)\left(\frac{R_L}{r_x}+1\right)-1\right]T,\ A_o \geq 10 \tag{19}$$

or

$$\tau_a=\frac{1}{4f}\left[4\left(\frac{R_L+r_x/2}{R_c}\right)\left(\frac{N_c}{N_x}\right)^2+\left(\frac{R_L+r_x/2}{r_x/2}\right)\right],\ A_o \geq 10 \tag{20}$$

The foregoing expressions are in agreement with the previous work of Storm.[6]

Step-Function Response

A consistent half-cycle average type of analysis precludes the representation of the saturable-reactor input or output as anything but constant at the average value over each half-cycle. The nor-

malized response of the saturable reactor to a step-function input is presented in Fig. 9. It is of particular interest to note that for values of $(2A_o-1)/2$, i.e., τ_a/T, equal to or greater than one, i.e., $A_o \geq 1.5$, at least 63% response is achieved at time $t=[(2A_o-1)/2](T)$. Thus, τ_a can be referred to as the 63% response time for values of A_o equal to or greater than 1.5. Clearly there is no half-cycle delay associated with the response of the saturable reactor such as is characteristic of the self-saturating amplifier. In fact, the only lower limit on the response time of the series saturable reactor is a practical limit imposed by the maximum control-circuit resistance which can be utilized. Obviously, it must be realized that any change in output power which is achieved during the first half-cycle must be supplied directly from the signal source via transformer action.

Gain-Bandwidth Product

An important parameter associated with amplifiers in general is the gain-bandwidth product. If one defines the saturable-reactor bandwidth as corresponding to the break frequency ω_o, simple expressions for the gain-bandwidth product $K\omega_o$ can be derived. For the series saturable reactor

$$K=(N_x/N_c)(A_i)$$

and

$$\omega_o=\left(\frac{\omega_c}{\pi}\right)\left(\frac{2}{2A_o-1}\right),\ A_o\geq 5$$

Substituting $A_o=(A_i+1)/2$ and simplifying produces the following equation:

$$(K\omega_o)=2\left(\frac{N_x}{N_c}\right)\left(\frac{\omega_c}{\pi}\right),\ A_o\geq 5 \text{ or } A_i'\geq 9 \quad (21)$$

It is interesting to note that the gain-bandwidth product of the self-saturating amplifier was shown to be[3]

$$(K\omega_o)=\left(\frac{N_x}{N_c}\right)\left(\frac{\omega_c}{\pi}\right),\ A_i\geq 9 \quad (22)$$

The dependence of the bandwidth of the parallel saturable reactor on the R_L/r_x ratio makes it impossible to derive a simple general expression for the gain-bandwidth product.

A plot of gain versus normalized frequency is presented in Fig. 10 to more clearly describe the series saturable reactor over its complete operating range, which includes that region in which the gain-bandwidth product is not constant. For comparison purposes an asymptotic plot of the corresponding information which has been obtained from the simple self-saturating magnetic amplifier is presented in Fig. 11.

Series Saturable Reactor with External Feedback

The application of 100% positive-current feedback to the series saturable reactor is illustrated in Fig. 12 for the simple case in which the number of turns in the positive-feedback winding N_f is equal to the number of turns in the load winding N_x.

The block diagram for this amplifier, shown in Fig. 13, is almost identical to that of the self-saturating magnetic amplifier, shown in Fig. 14. The transfer function is

$$KG(s)=\left[(2A_i)\left(\frac{N_x}{N_c}\right)\right]\times \left[\frac{\epsilon^{-Ts}}{(A_i+1)-(A_i)\epsilon^{-Ts}}\right] \quad (23)$$

The foregoing can be compared with the following transfer function for the simple self-saturating amplifier.

$$KG(s)=\left[(A_i)\left(\frac{N_x}{N_c}\right)\right]\times \left[\frac{\epsilon^{-Ts}}{(A_i+1)-(A_i)\epsilon^{-Ts}}\right] \quad (24)$$

It can be seen by inspection that the gain-bandwidth product of the saturable reactor with 100% positive feedback is double that of the self-saturating circuit. As would be expected, the addition of feedback to the saturable reactor has no effect on its gain-bandwidth product.

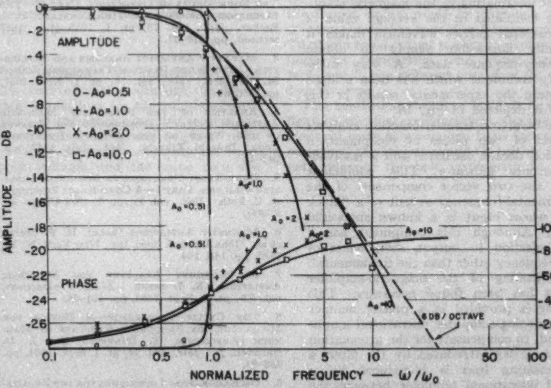

Fig. 17. Comparison of experimental operation with theoretical operation for the series saturable reactor

Parallel Saturable Reactor as a Self-Saturating Amplifier with Rectifier Leakage

An interesting comparison between the parallel saturable reactor and the self-saturating (doubler) magnetic amplifier can be obtained by treating the former circuit as the limiting case of a self-saturating circuit with rectifier leakage. The block diagram for the doubler circuit of Fig. 15 is presented in Fig. 16. Note that if the rectifier leakage resistance R_r goes to infinity, the block diagram reduces to that of the simple self-saturating circuit (Fig. 14). However, if the leakage resistance is zero, the block diagram becomes that of the parallel saturable reactor; see Fig. 3(B).

Experimental Verification of the Theory

The results of an effort to experimentally verify the validity of the transfer functions which have been derived are presented in Fig. 17. A brief discussion of the experimental techniques which have been used is presented in Appendix II.

Conclusions

A block-diagram method of analysis has been extended from the self-saturating class of magnetic amplifiers to the saturable-reactor class of magnetic amplifiers. It has been shown that a single theory of operation can be used to treat a variety of magnetic-amplifier circuits. The block-diagram method of analysis is submitted as a useful tool not only for the analysis of conventional circuits but as a means of synthesizing new types of circuitry.

Appendix I. Development of Block-Diagram for Series Saturable-Reactor

The voltage-loop equation for the control circuit, Fig. 1(A), during the $(n-1)$th half-cycle is

$$\bar{e}_g'(n-1)T+\bar{i}_c(n-1)TR_c-\bar{e}_c(n-1)T = \bar{e}_r'(n-1)T \quad (25)$$

In the load circuit, assuming $\bar{R} \gg (R_L+r_x)$,

$$\bar{e}_r(n-1)T+\bar{e}_g(n-1)T=E_s-\bar{e}_o(n-1)T \quad (26)$$

and

$$\bar{e}_r(nT)+\bar{e}_g(nT)=E_s-\bar{e}_o(nT) \quad (27)$$

Since

$$|\bar{e}_r'(n-1)T|=(N_c/N_x)|\bar{e}_r(n-1)T| =(N_c/N_x)|\bar{e}_g(nT)| \quad (28)$$

Fig. 18. Block diagram of test setup used in obtaining experimental results of Fig. 17

equation 25 may be rewritten as

$$[-e_c(n-1)T+\bar{i}_c(n-1)TR_c+\bar{e}_g(n-1)T]\times (N_x/N_c)=\bar{e}_g(nT) \quad (29)$$

With the use of equation 27 it can be seen that

$$\bar{e}_o(nT)=\bar{E}_s-\bar{e}_r(nT)-[-\bar{e}_c(n-1)T+ \bar{i}_c(n-1)TR_c+\bar{e}_g'(n-1)T](N_x/N_{cs}) \quad (30)$$

Taking the Laplace transform yields the following:

$$\bar{e}_o(s)=\bar{E}_s(s)-\bar{e}_r(s)-[-\bar{e}_c(s)+\bar{i}_c(s)R_c+ \bar{e}_g'(s)][N_x/N_c)\epsilon^{-Ts} \quad (31)$$

In Fig. 2, $\bar{i}_c(s)R_c=(N_x/N_c)\bar{i}_L(s)R_c$, etc.

Appendix II. Experimental Technique

The problem of experimentally determining the dynamic characteristics of the magnetic amplifier is a relatively difficult one which has been approached in a variety of ways in the past.[7-9] Although the magnetic amplifier most readily lends itself to the measurement of transient response, frequency-response information is normally more valuable for purposes of control system design. The fact that the output information of the magnetic amplifier is contained in the average value of the distorted carrier waveform makes it normally impossible simply to obtain frequency-response data. A very satisfactory technique which has been utilized to obtain the experimental results in this paper is depicted in Fig. 18.

The Solartron transfer-function analyzer consists of two pieces of equipment, a precision decade oscillator and a resolved-components indicator. This equipment yields the two vector components of the fundamental-frequency output of a "black box" whose input is a known sinusoidal signal. Although this equipment has a high rejection to output components of any frequency other than the fundamental, some filtering of the magnetic-amplifier output has been found necessary. This filtering is provided in a precise manner by an analog-computer operational amplifier and, to compensate for the attenuation and phase lag introduced by the filter, a compensating lead is introduced by a second operational amplifier between the decade oscillator and the magnetic-amplifier input. The use of operational amplifier filters rather than simple passive networks is necessary for two reasons. First, the magnetic-amplifier input impedance is a function of frequency and, therefore, a passive lead network on the input would see a variable rather than a constant load. Obviously this would not allow for proper compensation of the lag introduced by the output filter. The use of operational amplifiers effectively circumvents this problem. Second, the effective signal-source impedance of the oscillator, lead-network combination is frequency-dependent and therefore does not permit the simple determination of the effective resistance in the control circuit R_c. The extremely low (approximately 1 ohm) output impedance of the operational amplifier permits the assumption of a zero-impedance signal source.

This frequency-response method of evaluating the dynamic performance of magnetic amplifiers has been found to be not only valuable, but essential, in measurements on fast-response saturable reactors.

Discussion

A. G. Milnes (Carnegie Institute of Technology, Pittsburgh, Pa.): The author by comparing equations 23 and 24 reaches the conclusion that the gain-bandwidth product of a saturable reactor with 100% positive current feedback is double that of a self-saturating circuit. Such a statement assumes that N_x in both equations has the same value, whereas comparison on a physical basis shows that the numerical value of N_x in equation 23 should be half that of N_x in equation 24, and therefore the two circuits are substantially the same in gain-bandwidth product.

For example, consider the circuits constructed in turn from the same pair of cores (which is the logical physical comparison that should be made) and assume that each core has N turns capable of carrying load current and N_c turns rated for control current. Then, in the self-saturating connection, $N_x = N$; but with the same cores rearranged in the series circuit, with the same supply voltage, the gate turns per core become $1/2N(=N_x$ in equation 23) and the 100% feedback winding accounts for the remaining $1/2N$ turns per core. The conclusion that follows is that the two circuits are similar in voltage-gain-bandwidth product.

Since positive feedback does not alter the voltage-gain-bandwidth product of the series saturable-reactor circuit, it may be suggested that the feedback be omitted thus permitting N_x in equation 23 to be increased. This however considerably reduces the current gain of the series circuit and so lowers the power-gain-bandwidth product which is a matter of practical concern, and invalidates this method of comparison.

The relative merits of self-saturating and series reactor connections in static and transient response have been of interest to designers for many years and discussion can be found in the literature on this subject. In particular, the equivalence of gain-bandwidth products has been derived by relatively simple time-constant analysis in past papers.

R. M. Hubbard: Mr. Milnes is correct in his observation that although the fundamental expressions for the gain-bandwidth product of the series saturable reactor and that of the self-saturating amplifier differ by a factor of two, the assumption of equal supply voltages and the same core size dictates a factor of two difference in load-winding turns, thus making the two expressions equivalent. However, since I do not feel justified in making such an assumption an implicit part of the subject expressions, I actually erred in not comparing equations 23 and 24 in the same fashion that I compared equations 21 and 22, i.e., by simply drawing the reader's attention to the factor of two difference. By thus allowing the reader to supply his own assumed basis for comparing the two circuits, the author allows for other assumptions which are equally as valid as the one of identical supply voltages and core sizes. For example, consider the case in which a series saturable reactor with 100% feedback and a self-saturating amplifier are operating under thermally limited conditions with equal sinusoidal supply voltages. At maximum output, the load-winding-current form factor of the former circuit will be 1.11, while that of the latter circuit will be 1.57. Thus the load winding of the self-saturating circuit must utilize wire of approximately 40% greater cross section than in the case of the series saturable reactor. It can be seen that if the load winding and feedback winding of the saturable reactor occupy an area A, then the load winding of the self-saturating circuit must occupy an area $1.4 \times A$. Thus, in this case, the assumption of identical core sizes is not necessarily justified and, in fact, to validate Mr. Milnes' argument one must select a core for the self-saturating circuit which has an equal cross-sectional area and 40% greater window area than that of the saturable reactor.

Again, consider the case in which the two circuits are operating under resistance-limited conditions, and one chooses to obtain maximum power output by substantially matching the load resistance to the load-winding resistance. Clearly, using identical cores and supply voltages, it can be seen that the total load-circuit resistance in the case of the saturable reactor with 100% feedback is double that of the self-saturating circuit. Thus, under matched conditions, the obtainable load power in the case of the former circuit would be only one half of that obtainable from the latter circuit. To obtain equal output powers as a common basis for comparison, one would again be forced to use different core sizes for the two circuits.

The conclusion therefore is that, in the light of practical considerations, the use of identical cores as a common basis for comparison of the subject circuits is neither the only one nor the best assumption to be made. Thus the assumption that the number of turns in the load winding of the series saturable reactor is one half that of the equivalent self-saturating circuit is by no means the rule, and one can not with assurance make a general statement about the ratio of the gain-bandwidth products of the two classes of circuits.

I take exception to Mr. Milnes' contention that the gain-bandwidth product is invalid as a means of comparing the saturable reactor with feedback to the one without it. I would heartily agree if he had said that this is not the only parameter which is valuable for such a comparison. The importance of figure of merit or dynamic power gain is a well-known fact and I failed to explicitly mention this parameter because, as it applies to the self-saturating circuit, it was treated in some detail in an earlier paper[1] and also because the dynamic power gain for the series saturable reactor is very simply the product of current gain and gain-bandwidth product. Most certainly it does not follow that if the gain-bandwidth product is invariant with feedback then the feedback is extraneous.

The important point is that a saturable reactor, upon the application of feedback, is as well behaved as any other class of amplifier, be it vacuum-tube, transistor, etc., i.e.:

1. Feedback does not alter the gain-bandwidth product.
2. Voltage feedback does not alter the current gain and therefore does not alter the dynamic power gain.
3. Current feedback does alter the current gain and thereby alters the dynamic power gain.

In conclusion, I would like to point out that my purpose in presenting this block-diagram method of analysis was to show that there is a single method of analysis which can be applied to all classes of magnetic-amplifier circuits to yield results which are substantially in agreement with the results obtained by a variety of other methods both theoretical and emperical. In addition to the advantage of not requiring a different method of analysis for each class of circuit, this technique, I feel, sheds some light on the operation in the regions of fast response, which are excluded from most other techniques.

The Effective Feedback Factor of Self-Balancing Magnetic Amplifiers

W. A. GEYGER
MEMBER AIEE

Synopsis: The effective feedback factor of a magnetic amplifier is a measure for the stability of operation (drift). In conventional forms of external-feedback or self-saturating circuits, the drift is linearly proportional to the actual value of ampere-turn gain. In these circuits, the drift can be reduced by reducing the extrinsic-feedback factor. However, because the ratio of gain reduction over drift reduction is constant, the gain will be reduced at the same rate.

In self-balancing magnetic amplifiers, a very significant reduction of drift is obtained by reducing the effective (total) feedback factor. This has been achieved by combination of the dynamic gain-increasing effect of magnetic positive feedback and the drift-reducing effect of electric negative feedback, resistance-coupled into the control-circuit loop.

This paper is concerned with the determination of the effective (total) feedback factor of self-balancing magnetic amplifiers. The basic considerations may be applied equally well to single-ended and push-pull circuits utilizing either external feedback or self-saturation. Typical examples of voltage-balance and current-balance forms of self-balancing magnetic-amplifier circuits are presented to demonstrate the practical significance of the simple equations with regard to design considerations on the stability of operation of such circuits.

THE ordinary saturable reactor is characterized by the fact that, over certain ranges, the average value of load current is substantially independent of large variations in magnitude, frequency, and waveshape of the power-supply voltage, and considerable changes in load resistance. With regard to these unique features, it is possible to employ ordinary saturable reactors with high-permeability rectangular-hysteresis-loop core material as d-c instrument transformers for measurement of large direct currents and high direct voltages.[1,2] This possibility is based upon the current-transformer character (law of equal ampere-turns[3]) which is the result of inherent negative-feedback properties (intrinsic negative feedback) of the ordinary saturable reactor having either series- or parallel-connected a-c load windings.

In conventional external-feedback or self-saturating types of magnetic-amplifier circuits, extrinsic positive feedback is provided for reducing or nearly nullifying the intrinsic negative feedback of the ordinary saturable reactor to obtain certain static and dynamic performance characteristics, as expressed, e.g., by ampere-turn gain, power gain, control time constant, and dynamic power gain. In these types of magnetic-amplifier circuits, the effective feedback ratio[4] or total feedback factor[3] is a measure for the stability of operation (drift). The drift is linearly proportional to the ampere-turn gain and may be reduced by reducing the extrinsic-feedback factor. However, because the ratio of gain reduction over drift reduction is constant, the gain will be reduced at the same rate.

The aim of the research and developmental work on magnetic amplifiers of the self-balancing potentiometer type[5,6] consisted in combining the inherently extremely stable operating conditions of the ordinary saturable reactor, as used in d-c instrument transformers,[1,2] with the unique features of high-precision self-balancing potentiometer devices and negative-feedback amplifiers. In these self-balancing magnetic amplifiers, extrinsic magnetic positive feedback (external feedback or self-saturation) is provided for completely nullifying the intrinsic negative feedback of the ordinary saturable reactor (infinite internal gain or critical regeneration[5,6]). Additionally, extrinsic electric negative feedback (resistance-coupled into the control-circuit loop) is applied to obtain very stable operating conditions of the amplifier, similar to those of d-c instrument transformers. In self-balancing magnetic amplifiers, a very significant reduction of drift is obtained by reducing the effective (total) feedback factor. This has been achieved by combination of the dynamic gain-increasing effect of magnetic positive feedback and the drift-reducing effect of electric negative feedback. Operating under voltage-balance or current-balance conditions of the control circuit, these amplifiers demand practically no energy from the d-c signal source. Because the average value of the control-winding current is substantially zero for the entire working range of the amplifier, the linearity error is in the order of 1/10 of 1% or less. Over certain ranges, large variations in magnitude and frequency of power-supply voltage, load resistance, and control-circuit resistance have no appreciable effect upon the transconductance, voltage ratio, current ratio, or transresistance. Such amplifiers operate under very stable conditions with a large over-all power gain and a high speed of response. When using 100% negative feedback,[7,8] actual response time may be reduced to its minimum value of one half-cycle of the power-supply frequency. On the other hand, for special applications, the transient-response characteristics may be altered materially through the use of differentiating or integrating circuit elements in the degeneration network of the amplifier. Results of various experimental investigations show that the actual behavior of self-balancing magnetic amplifiers approximates very closely corresponding characteristics of an ordinary saturable reactor with stabilizing negative-feedback properties (intrinsic negative feedback).

This paper is concerned with the determination of the effective (total) feedback factor of self-balancing magnetic amplifiers. The basic considerations may be applied equally well to single-ended and push-pull circuits utilizing either external feedback or self-saturation. Typical examples of voltage-balance and current-balance forms of self-balancing magnetic-amplifier circuits are presented to demonstrate the practical significance of the simple equations with regard to design considerations on the stability of operation of such circuits.

Effective Feedback Factor of Single-Ended Self-Balancing Magnetic Amplifiers

VOLTAGE-BALANCE EXTERNAL-FEEDBACK CIRCUIT

In the circuit of Fig. 1, the d-c signal voltage E_S is balanced by the compensating voltage $E_K = I_L R_K$. The average value of control-winding current is, if I_C is very small in comparison with I_L,

$$I_C=\frac{E_S-E_K}{R_C+R_K}=\frac{E_S}{R_C+R_K}-\frac{E_K}{R_C+R_K}=I_S-I_K \quad (1)$$

where E_S is the electromotive force of

Paper 57-767, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting, Montreal, Que., Canada, June 24–28, 1957. Manuscript submitted March 11, 1957; made available for printing July 9, 1957.

W. A. GEYGER is with the U. S. Naval Ordnance Laboratory, Silver Spring, Md.

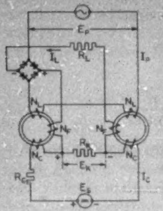

Fig. 1. Self-balancing magnetic amplifier of voltage-balance external-feedback type. Transconductance of this circuit is $I_L/E_S = 1/R_K$, and effective feedback factor is $h = -(N_C/N_L)R_K/(R_C+R_K)$

the d-c signal source, and R_C is the total resistance of the control circuit between the terminals of negative-feedback resistor R_K (including the sum of the resistances of the control-winding units N_C, and the internal resistance of the signal source). The term $I_S = E_S/(R_C+R_K)$ is the signal-current component, and $I_K = E_K/(R_C+R_K)$ is the compensating-current component.

It was shown[5] that the relationship between average value of load current I_L and signal voltage E_S is given by the equations

$$\frac{E_S - I_L R_K}{R_C+R_K} = I_L \frac{N_L - N_F}{N_C} \tag{2}$$

or

$$\frac{E_S}{I_L} = R_K + (R_C+R_K)\frac{N_L-N_F}{N_C} \tag{3}$$

Thus, with $N_F = N_L$, the following results

$$\frac{E_S}{I_L} = R_K \text{ or } \frac{I_L}{E_S} = \frac{1}{R_K} \tag{4}$$

where $1/R_K$ represents the transconductance of the circuit. In this case

$$I_C = I_S - I_K = 0 \tag{5}$$

The condition, $N_F = N_L$, corresponding to critical regeneration,[8] involves the assumption of ideal properties of the saturable-reactor elements and feedback rectifiers. This assumption means that the rectifier output current I_L has exactly the average value of the rectifier input current I_P. In practice, however, departure of the saturable-reactor and rectifier components from the ideal characteristics may cause a certain reduction of current ratio I_L/I_P so that actual external-feedback ampere-turns $I_L N_F$ are correspondingly reduced.

To compensate for imperfections of the saturable reactors and rectifiers, the number of turns of external-feedback windings N_F may be correspondingly increased. Another practical possibility consists in providing an additional positive-feedback circuit containing a current-divider network with boosting windings. In this way, it is possible to apply fractional turns[9] for proper adjustment ($I_C = 0$).

With regard to the following considerations, the method of obtaining the desired critical-regeneration condition is not important. Actually, in any case, the extrinsic positive-feedback ampere-turns will be adjusted so that the intrinsic negative feedback of the saturable reactor is completely nullified, and the average value of I_C is substantially zero. Therefore, to simplify the following equations, it is assumed that critical regeneration ($I_C = 0$) is obtained with $N_F = N_L$.

The magnitude of the intrinsic negative feedback of the ordinary saturable reactor can be expressed by the intrinsic-feedback factor $h_i = -1$, as defined by H. F. Storm,[3] where h_e designates the extrinsic-feedback factor, and $h = h_e + h_i = h_e - 1$ represents the total or effective feedback factor of the saturable reactor with extrinsic positive feedback. The special form of compound-feedback circuitry, as used in the circuit of Fig. 1, utilizes two separate and fundamentally different extrinsic-feedback components, and therefore involves two separate extrinsic-feedback factors: the positive extrinsic-feedback factor $h_{e,m}$ corresponding to the positive magnetic feedback, which is produced by the external-feedback windings N_F; and the negative extrinsic-feedback factor $h_{e,e}$ corresponding to the negative electric feedback, which is produced by the control windings N_C acting as negative-feedback windings.

In accordance with Storm's concept,[3] the effective or total feedback factor of the circuit, Fig. 1, is defined as follows:

$$h_i = -1,\ h_{e,m} = I_L N_F / I_P N_L = N_F/N_L = +1,$$

and

$$h_{e,e} = -I_K N_C / I_P N_L = -(I_L N_C / I_P N_L) \times R_K/(R_C+R_K) = -(N_C/N_L)R_K/(R_C+R_K)$$

Therefore

$$h = h_i + h_{e,m} + h_{e,e} = h_{e,e} = -\frac{N_C}{N_L}\frac{R_K}{R_C+R_K} \tag{6}$$

Furthermore, the remaining amount of applied positive feedback may be characterized by the resultant extrinsic-feedback factor

$$h_e = h_{e,m} + h_{e,e} = 1 - \frac{N_C}{N_L}\frac{R_K}{R_C+R_K} \tag{7}$$

When expressing the remaining amount of applied positive feedback in per cent,[10] the following equation may be used:

$$F_{eff} = +100\left(1 - \frac{N_C}{N_L}\frac{R_K}{R_C+R_K}\right)\% \tag{8}$$

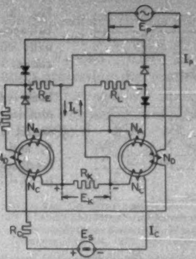

Fig. 2. Self-balancing magnetic amplifier of voltage-balance self-saturating type. Transconductance of this circuit is $I_L/E_S = 1/R_K$, and effective feedback factor is $h = -2(N_C/N_A)R_K/(R_C+R_K)$

The practical significance of these simple relationships with regard to design considerations may be demonstrated by three typical examples:

1. With $(N_C/N_L)R_K/(R_C+R_K) = 1.0$, the effective feedback factor is $h = -1$, and $F_{eff} = 0$. In this case, with regard to stability of operation, the behavior of the circuit of Fig. 1 is equivalent to that of the ordinary saturable reactor which is characterized by the intrinsic-feedback factor $h = h_i = -1$, i.e., the circuit has maximum stability of operation.
2. With $(N_C/N_L)R_K/(R_C+R_K) = 0.1$, the effective feedback factor is $h = -0.1$, the resultant extrinsic-feedback factor is $h_e = +0.9$, and $F_{eff} = +90\%$ corresponding to the turns ratio $N_F/N_L = 0.9$ of a conventional-type external-feedback circuit.[10]
3. With $R_K = 0$ and $h = 0$, i.e., when the electric negative feedback is completely removed, the circuit of Fig. 1 becomes unstable ("trigger effect" or "snap action").

VOLTAGE-BALANCE SELF-SATURATING CIRCUIT

In the circuit of Fig. 2, magnetic positive feedback is produced by self-saturation.[11] Electric negative feedback is produced by the control windings N_C acting as negative-feedback windings. Additionally, a small amount of magnetic positive feedback is produced by the external-feedback circuit $R_E R_D N_D$ to compensate for imperfections of the saturable reactors and rectifiers. In this circuit, critical-regeneration condition ($I_C = 0$) is obtained by adding the positive extrinsic-feedback effect of the self-saturating circuit and the small additional positive-feedback effect of the "boosting circuit" $R_E R_D N_D$. In this case, the effective or total feedback factor is defined in a similar way:

$$h_i = -1,\ h_{e,m} = +1,$$

and

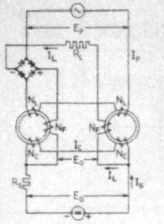

Fig. 3. Self-balancing magnetic amplifier of current-balance external-feedback type. Current ratio of this circuit is $I_L/I_S=1$, and effective feedback factor is $h=-N_C/N_L$

$$h=h_{e,e}=-2\frac{N_C}{N_A}\cdot\frac{R_K}{R_C+R_K} \tag{9}$$

The only difference is that in the circuit of Fig. 1 the total amount of magnetic positive feedback is produced by the external-feedback windings N_F (and sometimes by additional external-feedback windings providing the fractional turns[9]), whereas in the circuit of Fig. 2 the major part of magnetic positive feedback is produced by the self-saturating circuit, i.e., by means of the gate windings N_A with the associated half-wave rectifier elements. However, the corresponding positive extrinsic-feedback factor, $h_{e,m}=+1$, is the same in both cases.

CURRENT-BALANCE EXTERNAL-FEEDBACK CIRCUIT

In the circuit of Fig. 3, the signal current I_S is balanced by the opposing load current I_L, and the control-winding current $I_C=I_S-I_L$ is substantially reduced to zero as a result of critical regeneration ($N_F=N_L$). This arrangement operating under current-balance conditions of the control circuit is characterized by the fact that the effective input resistance of the magnetic amplifier is greatly reduced, and the actual voltage drop across the control windings N_C is substantially reduced to zero. In contrast to the voltage-balance circuits, Figs. 1 and 2, which act as voltmeters having very high resistances, the current-balance circuit of Fig. 3 acts as an ammeter having a very low resistance and a very small voltage drop across its terminals.

The effective feedback factor of the circuit in Fig. 3 is given by

$$h_i=-1,\ h_{e,m}=N_F/N_L=+1,$$

and

$$h_{e,e}-\frac{N_C}{N_L}$$

Therefore,

$$h=h_i+h_{e,m}+h_{e,e}=h_{e,e}=-\frac{N_C}{N_L} \tag{10}$$

With $N_C=N_F=N_L$, $h_{e,e}=-1$, and $F_{eff}=0$, i.e., the circuit has maximum stability of operation. It is to be noted that the total amount of load current I_L is superposed upon the signal current I_S. Thus, the current ratio $I_L/I_S=1$. The unique feature of this circuit is the fact that the input voltage E_0 of the amplifier is reduced to an extremely small value which is about 1,000 times smaller than the voltage drop across the control windings of the ordinary saturable reactor. However, the stability of operation, as characterized by the effective feedback factor $h=h_i=h_{e,e}=-1$, is the same in both cases.

CURRENT-BALANCE SELF-SATURATING CIRCUIT

In the circuit of Fig. 4, similar to that of Fig. 2, magnetic positive feedback is produced by self-saturation; and electric negative feedback is produced by the control windings N_C acting as negative-feedback windings. Additionally, a small amount of magnetic positive feedback is produced by the external-feedback circuit $R_ER_DN_D$ to compensate for imperfections of the saturable reactors and rectifiers. In contrast to the current-balance circuit of Fig. 3, a well-defined fraction of load current I_L is superposed upon the signal current I_S to increase the current ratio or current gain I_L/I_S of the amplifier:

$$\frac{I_L}{I_S}=\frac{R_1+R_2}{R_1}=\frac{I_L}{I_K} \tag{11}$$

This current ratio can be conveniently adjusted by a current-divider potentiometer resistor (Ayrton-Mather shunt). The control-winding current $I_C=I_S-I_K$ is substantially reduced to zero, and $E_0=0$.

The effective feedback factor of the circuit of Fig. 4 is given by

$$h_i=-1,\ h_{e,m}=+1,$$

and

$$h=h_{e,e}=-2\frac{N_C}{N_A}\,\frac{R_1}{R_1+R_2} \tag{12}$$

Therefore, e.g., with $2(N_C/N_A)R_1/(R_1+R_2)=0.05$, the effective feedback factor is $h=-0.05$, the resultant extrinsic-feedback factor is $h_e=+0.95$, and $F_{eff}=+95\%$, corresponding to the turns ratio $N_F/N_L=0.95$ of a conventional-type external-feedback circuit.[13]

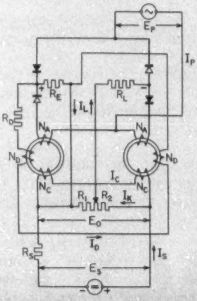

Fig. 4. Self-balancing magnetic amplifier of current-balance self-saturating type. Current ratio of this circuit is $I_L/I_S=(R_1+R_2)/R_1$, and effective feedback factor is $h=-2(N_C/N_A)R_1/(R_1+R_2)$

Effective Feedback Factor of Push-Pull-Type Self-Balancing Magnetic Amplifiers

GENERAL

The preceding considerations may be easily extended to the various forms of push-pull-type self-balancing magnetic amplifiers utilizing either external feedback or self-saturation for obtaining the critical-regeneration condition: $h_{e,m}=+1$. Generally, in such arrangements containing two single-ended external-feedback or self-saturating circuits in back-to-back connection, each of these circuits has its own positive-feedback component which completely nullifies the intrinsic negative feedback ($h_i=-1$) of the saturable reactor.[5,6,13–16] In another arrangement[17] with two separately biased saturable reactor systems utilizing differential feedback,[18,19] the resultant positive-feedback component of the magnetic amplifier is proportional to the actual difference between the individual load currents and is zero with no-signal conditions. This type of push-pull arrangement has proved to be very suitable for magnetic instrument amplifiers to be used in the realm of instrumentation, control engineering, and analog-computer techniques.

When designing such self-balancing magnetic amplifiers of the differential-feedback type,[17] determination of the effective feedback factor is of utmost importance. The larger the amount of negative-feedback ampere-turns (I_KN_C), the better is the stability of the amplifier with regard to zero drift and constant gain (linearity error). Therefore, such amplifiers are a representative example for illustrating the considerations on push-pull circuitry.

DETERMINATION

With respect to the determination of the effective feedback factor of differential-feedback self-balancing magnetic amplifiers, it was shown[17] that in such

Vol,
Pt. 1
1958

amplifiers critical regeneration is obtained with $N_F = N_L/2$. Thus, in this special case, the effective feedback factor is given by

$$h_i = -1,\ h_{e,m} = 2N_F/N_L = +1,$$

and

$$h_{e,e} = -2(N_C/N_L)R_K/(R_C+R_K)$$

Therefore

$$h = h_i + h_{e,m} + h_{e,e} = -2\,\frac{N_C}{N_L}\,\frac{R_K}{R_C+R_K} \qquad (13)$$

Evidently, the only difference between equations 6 and 13 is that in the single-ended external-feedback circuit of Fig. 1

$$h_{e,m} = N_F/N_L = +1,$$

and

$$h_{e,e} = -(N_C/N_L)R_K/(R_C+R_K),$$

whereas in the differential-feedback push-pull circuit,[17]

$$h_{e,m} = 2N_F/N_L = +1,$$

and

$$h_{e,e} = -2(N_C/N_L)R_K/(R_C+R_K)$$

Influence

The influence of the mixing network on the effective feedback factor of push-pull-type self-balancing magnetic amplifiers is discussed in the following. The relationship of equation 13 is based upon the assumption that a parallel mixing network or a twin-load mixing network is used for deriving the resultant polarity-reversible load current I_L from the individual load currents I_L' and I_L'' of the two saturable-reactor systems.[20] In this case:

$$I_L' = I_Q' + \Delta I_L',\quad I_L'' = I_Q'' - \Delta I_L'',$$

and

$$I_L = I_L' - I_L'' = 2\Delta I_L \qquad (14)$$

where $I_Q' = I_Q''$ are the quiescent-current values (the individual load currents with no-signal conditions) of the two saturable-reactor systems. Evidently, the factor 2 in equation 14 is responsible for the difference between equations 6 and 13.

When employing a series mixing network with mixing resistors R_S and load resistor R_L, the relationship between I_L', I_L'', and I_L is given by the equation[20]

$$I_L = (I_L' - I_L'')\,\frac{R_S}{2R_S+R_L} = 2I_L\,\frac{R_S}{2R_S+R_L} \qquad (15)$$

In this case, the negative-feedback ampere-turns (I_KN_C) are reduced by the resistance ratio $R_S/(2R_S+R_L)$ of the series mixing network with the passive resistance elements R_S; thus

$$h_{e,e} = -2\,\frac{R_S}{2R_S+R_L}\,\frac{N_C}{N_L}\,\frac{R_K}{R_C+R_K} \qquad (16)$$

These considerations illustrate the advantage of the use of parallel-type or twin-load mixing networks in push-pull-type self-balancing magnetic amplifiers.

Design Considerations

The relationship between the static characteristics (linearity error, power gain, zero-drift stability) and the transient performance (response time) of self-balancing magnetic amplifiers is such that if one property is accentuated, it is always at the expense of the other properties.[5] For example, it is generally desirable, in the interest of optimum linearity, to use as many control-winding turns (N_C) as the required response time will permit. In this way the inevitable residue of compensating ampere-turns which must be supplied by the control circuit will require a minimum of current (I_C) from that source, resulting in a minimum of linearity error.[18] Furthermore, the use of the greatest possible number of turns of N_C has the important added advantage of improving the stability of the amplifier by providing for a maximum of negative-feedback ampere-turns (I_KN_C).

On the other hand, in order to reduce actual response time of self-balancing magnetic amplifiers to its minimum value of one half-cycle of the power-supply frequency by introducing 100% negative feedback,[7,8] the number of turns of N_C must be reduced to smaller values. Analysis of the voltage-balance form of this amplifier[21] reveals that half-cycle response will be obtained if turns ratio $N_C/2N_L$ of external-feedback circuits (or the corresponding turns ratio N_C/N_A of self-saturating circuits) is approximately equal to the resistance ratio R_K/R_0 (the over-all voltage gain), where R_K is the actual value of the negative-feedback resistor, and R_0 is the total resistance of the output circuit including load resistance R_L, output-winding resistance, and forward resistance of the feedback rectifiers. Analysis of the current-balance form of the self-balancing magnetic amplifier reveals similar relationships.

Referring to practical values of the effective feedback factor of self-balancing magnetic amplifiers, it is to be noted that the resultant extrinsic-feedback factor, equation 7, characterizing the remaining amount of applied positive feedback, should not exceed values in the range $h_e = h_{e,m} + h_{e,e} = 0.95\ldots0.98$. This range of h_e corresponds to the turns ratio $N_F/N_L = 0.95\ldots0.98$ of a conventional external-feedback circuit ($F_{eff} = +95\%\ldots98\%$). With regard to this limitation, it is well to remember that with conventional external-feedback circuits utilizing a moderate amount of positive extrinsic feedback ($N_F/N_L = 0.5\ldots0.95$), the simple equation expressing the relationship between ampere-turn gain and turns ratio N_F/N_L holds to a good degree of accuracy (about 1% to 2%).[13]

THIS PAPER DESCRIBES a problem and one solution to the problem which arose during the logical design of a digital computer for the real-time simulation of airplane flight. The computer in question is a 1-address machine with magnetic core memory which performs the basic operations of addition, comparison, transfer from arithmetic unit to memory, etc., at the rate of one operation every 5 microseconds. The logic of the machine is realized in pulse-type diode switching circuits similar to those employed by the National Bureau of Standards Eastern Automatic Computer and operating at an allowable pulse repetition frequency of 1.2 megacycles.

Because a 1-address mode of operation had been selected for the computer, it was necessary to provide a sequencing counter to specify the address of the next instruction upon the completion of the preceding order. Whether the sequence of addresses should follow a conventional, fixed pattern or whether it should be determined by the logic of the sequencing counter was considered to be of academic interest; the flight simulator was felt to be a sufficiently special-purpose device to justify either: 1. the programmer's care in assigning instructions to the addresses, or 2. the construction of a slow-speed translation device to convert binary forms into their machine equivalents. The capacity to specify a sequence of addresses out of the normal sequence as the result of a conditional or unconditional operation was incorporated in the sequencing counter, but this will not be discussed; it requires only the resetting of the sequencing counter to specify an arbitrary address.

Requirements

Further specification of the sequencing counter resulted from the following: 1. The sequencing counter must be capable of storing an address within its own logical circuitry. 2. The transition time from one address to the next must be minimized. 3. The equipment must be minimized. 4. The specification of a series of addresses need not follow a true binary sequence. The requirements are stated in the following definition of a particular type of sequencing counter which is acceptable for the purposes at hand.

Definition

A zero time counter is an m-stage register (where m is a specified integer) which advances through all its 2^m distinct states in response to a sequence of 2^m input counts in such a manner that, in the transition from any state k to its successor state $k+1$, all m storage cells in the register make the transition in one logical step and simultaneously to within the switching-time tolerance of the cells.

Methods Considered

Two methods for constructing a zero time counter were considered. The first technique involves the storage of additional information with each order in the instruction memory. Stored and read out with the kth instruction are sufficient bits to specify the address of the $(k+1)$th instruction. During the performance of the kth instruction these bits are held in a register in the control unit. At the conclusion of the kth instruction the register is interrogated and the $(k+1)$th instruction is specified.

The second technique involves an m-stage register with 2^m stable states. Each stage acts as a storage cell except a counting pulse occurs; in the latter case, the new state of each stage is determined as a logical function of the previous states of some or all of the other stages. The register advances through all its 2^m distinct states in response to 2^m counting pulses; each state is used to specify the address of an order in the instruction memory.

Logic Notation

The logic notation used in the remainder of the paper is illustrated in Fig. 1 by a typical, pulse-type, OR-AND-OR pyramid with pulse power amplifier and transformer.

N, greater than one, clock phases ($CP1$, $CP2$, ..., CPN) are assumed per pulse time, thus dividing a pulse time into N equal time intervals of duration $1/N$ units of time; $1/N$ is the standardized delay through a pyramid and its amplifier. The delay line in Fig. 1 is of length $(1-1/N)$ pulse times (nominal), a length which insures that an output pulse X will be recirculated and arrive at gate 2 one pulse time after it was generated; hereafter, such a delay pulse will be referred to by its corresponding small case letter x. Delay lines of nominal length $(1-1/N)$ and $(1-2/N)$ pulse times will hereafter be referred to by the symbols α and β respectively.

The regeneration gate 1 and the clock pulse inputs to AND gates 2 and 3 are used only for synchronizing and shaping purposes, and will be omitted from the logical circuit equations. In the equations multiplication represents AND and addition represents OR; a prime indicates negation, thus X' means "not X" or "X is not present." In the type of circuit discussed in this paper negation is realized by the application of a negative output pulse X^* (generated simultaneously with X) to an inhibit input of a gate denoted by a circle; thus X' also means "X^* is not present at an inhibit input."

The logical equation of Fig. 1 is therefore

$$(X, X^*) = xA + (B+C)D'$$

meaning that there will be a positive output pulse X (and simultaneously a negative output pulse X^*) if and only if both x and A are present, or either B or C or both (but not D^*) are present.

Previous Techniques

Both techniques mentioned in the section "Methods Considered" have been used previously in the construction of sequencing counters for digital computers. However, neither has resulted in a device which meets the present requirements. The purpose of this section is to outline previous methods of sequencing an instruction memory and discuss their limitations.

Paper 57-199, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 21–25, 1957. Manuscript submitted August 8, 1956; made available for printing September 13, 1957.

Fig. 2. Memory-sequenced conventional counter

MEMORY-SEQUENCED DEVICE

Fig. 2 illustrates a 32-word instruction memory, a 3-by-2 into 8-by-4 decoder, and a 5-stage dynamic register for sequencing the addresses. With each instruction are stored five additional bits (160 total) which are used to specify the address of the next order and which may be selected arbitrarily by the programmer.

Assume that the address of the instruction to be performed next in sequence is set up in the dynamic register. *A* gates the address into the decoder which specifies the proper memory location; both the instruction and its five additional bits are read out. The latter, which have been selected to specify the address of the next instruction, are gated by *S*, *S** into the dynamic register, replacing its previous contents.

Several comments are in order. First, the address of the instruction being performed is never available because the register is immediately advanced to the address of the next order. This may be remedied by: 1. reading the new address out of the memory into a second 5-stage dynamic register, and 2. gating the new address from the second register into the first at the conclusion of the current instruction. However, this alteration approximately doubles the amount of dynamic circuitry involved.

Second, the method requires the storage of $m2^m$ extra bits in the instruction memory in the general case. If the memory is a magnetic core matrix array, m additional matrices and their associated read out amplifiers and rewrite drivers are required.

Third, the technique is economically feasible only when the memory system and its associated selection equipment are already an integral part of the system. Furthermore, the speed of the sequencing device is limited by the access time of the memory. These last comments are not pertinent to the problem at hand but are made with reference to the general problem of constructing counters.

CONCERNING 2^m STABLE-STATE BINARY COUNTERS

Figs. 3 and 4 illustrate two previous alternatives to a memory-sequenced device. The examples taken are 5-stage counters with 32 stable states which follow a true binary sequence when triggered by *S*, *S**; both counters retain their states between applications of *S*, *S**. The decoder and instruction memory are omitted from the drawings since there are no feedback loops in the system.

The salient characteristic of the counter of Fig. 3 is that it operates on a ripple-carry basis. Application of (*S*, *S**) inverts the state of stage 1 and possible carries propagate through the remaining stages. The outputs of all the stages may not be read simultaneously until the *CP*1 following the application of (*S*, *S**), or four clock phases later. Furthermore, since the counter must drive pyramids in the decoder which are all clocked at the same phase (*CP*2), additional delay lines must be inserted in the outputs of stages 2, 3, and 4. (This last comment is also pertinent to the resetting of the counter to an arbitrary address when the drivers have a common clock phase.)

The 5-stage counter of Fig. 4 solves the ripple-carry problem by anticipating possible carries in combinational circuits. The transition from state k to state $k+1$ is made simultaneously in all stages at time *CP*1, and no delay lines need be inserted between the counter and the decoder. However, the logical complexity of the AND gates in the anticipatory carry pyramids is greater, the more significant the stage.

In summary, with the use of previous techniques it is possible to minimize equipment at the expense of ripple-carry time or vice versa; simultaneous minimization of both, however, does not appear to be feasible in a counter that follows a true binary sequence of states.

Shifting Counters

Returning to the definition of a zero time counter given in the section "Requirements," the anticipatory carry counter is obviously a special case, namely, a zero time counter which proceeds in true binary sequence. In an attempt to reduce equipment, other counting sequences were considered, with the requirement in mind of uniform minimum transition time. Since there are at least (2^m-1), different m-stage zero time counters, the following special class which offered hope of equipment minimization was investigated.

Consider such a closed sequence or ring of 2^m binary digits that any arrangement of m consecutive bits is represented once and only once in the complete ring. If, first, any m consecutive bits are sampled, and if the m consecutive bits displaced one digit to the left (right), etc., back to the starting point, are then sampled, all 2^m possible arrangements will have been encountered. Furthermore, every time the shift left (right) is made, only one new digit is encountered; the remaining $m-1$ digits were known from the previous number, and now simply appear shifted one place to the right (left) in the new number.

A counter operating on this principle

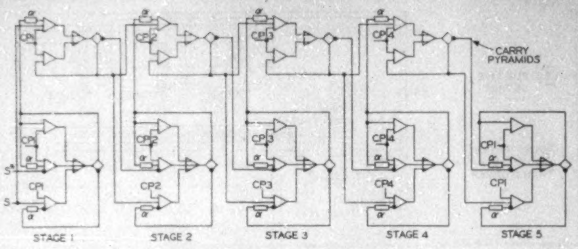

Fig. 3. Ripple-carry binary counter

can be mechanized using: 1. an m-stage shifting register, and 2. a logical circuit (or equivalent) which generates the next bit of the sequence as a function of the previous states of the m stages of the shifting register. To minimize equipment, it is necessary to design the simplest possible shifting register, and find that closed sequence which yields the least complex logical generator circuit. A method for generating the ring[1] and the number of different rings that exist[2] may be found in the literature. For m greater than 4, it is an overwhelming task to determine which ring possesses the simplest generator circuit. However, a few different rings have been developed for each value of m less than 7; the simplest rings of those investigated are presented in the section "Concerning 2^m Stable-State Shifting Counters." The section "Memory-Sequenced Device" illustrates a mechanization involving storage of the ring in the memory, a technique whereby generator complexity is of no consequence.

MEMORY-SEQUENCED DEVICE

Fig. 5 illustrates a 32-word instruction memory, a 3-by-2 into 8-by-4 decoder, and a 5-stage dynamic shifting register for sequencing the addresses. With each instruction is stored 1 additional bit (a total of 32) which forms part of the address of the next instruction.

Assume that the address of the instruction to be performed next in sequence is set up in the dynamic register. A gates the address into the decoder, which specifies the proper memory location; both the instruction and its additional bit are read out. (S, S^*) simultaneously gates the contents of stage 4 into stage 5, the contents of stage 3 into stage 4, . . . , and the bit from the memory into stage 1. The extra bit will have been selected once and for all by the programmer as the bit in the ring to the left of the m consecutive bits represented by the state of the shifting register before (S, S^*) occurred.

The same comments that were made regarding the memory-sequenced device of the section "Memory-Sequenced Device" are applicable here except that, first, only a single flip-flop need be inserted in the address output line in order to make available the address of the instruction which is being performed and, second, the method requires the storage of only 2^m bits.

CONCERNING 2^m STABLE-STATE SHIFTING COUNTERS

In those instances where it is not convenient to store the ring of 2^m bits, a logical generator circuit may be used as an alternative. Fig. 6 illustrates a 5-stage shifting register with a sequence generator pyramid to create the successive bits of the ring for insertion in stage 1 as a function of the previous states of the five register stages.

To simplify the hardware required to realize the logical equation for the generator circuit, it proves convenient to shift the primes of some of the register stages; doing so does not affect the uniqueness of each representation of m consecutive bits in the ring. Thus (S, S^*) gates the contents of stage 4 into stage 5, the inverse of stage 3 into stage 4, the inverse of stage 2 into stage 3, the contents of stage 1 into stage 2, and the output of the sequence generator into stage 1 whenever the address is to be changed.

A list follows of logical equations for shifting counters with m less than or equal to 6. The $m=2$, 3, and 4 counters represent the rings of those classes which are cheapest to synthesize using pulse-type, OR-AND-OR pyramids for logical gating. For $m=5$ and 6 many possible rings exist, and the counters listed represent the simplest of those that have been investigated (the $m=5$ counter is that shown in Fig. 6).

The logical equations for shifting counters with m greater than 6 were not investigated, although a ring for $m=12$ was obtained. It is a matter of speculation whether a shifting counter with m equal to 12, for example, may be more cheaply synthesized by providing the required generator circuit or by cascading counters of lower order. If an $m=12$ counter were formed from two $m=6$ counters, the equipment involved would be two generator circuits plus an additional pyramid to sense a particular state (say, all zeros) of the low-order counter. Whether this amounts to more or less equipment than the $m=12$ generator circuit is not known.

The counting sequence of the $m=5$ shifting counter of Fig. 6 is as given on the following page:

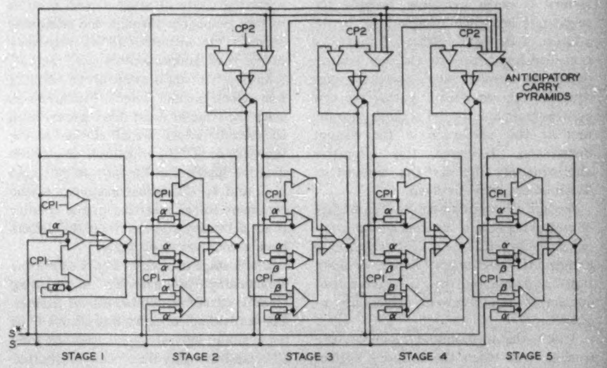

Fig. 4. Gated binary counter

Repeat				

Logical Equations

$m=2$ (4 states)
$A=Sg+S'a$
$B=Sa'+S'b$
$g=b$

$m=3$ (8 states)
$A=Sg+S'a$
$B=Sa'+S'b$
$C=Sb+S'c$
$g=[C(A+B)+A'B'C']$ delayed by β

$m=4$ (16 states)
$A=Sg+S'a$
$B=Sa'+S'b$
$C=Sb+S'c$
$D=Sc+S'd$
$g=[D(A+B+C)+A'B'C'D']$ delayed by β

$m=5$ (32 states)
$A=Sg+S'a$
$B=Sa+S'b$
$C=Sb'+S'e$
$D=Sc'+S'd$
$E=Sd+S'e$
$g=[AE'(B+C)+A'E(B+D)+B'C'E+B'CD'E'$ delayed by β

$m=6$ (63 states)
$A=Sfg+Sf'g'+S'a$
$B=Sa+S'b$
$C=Sb+S'c$
$D=Sc+S'd$
$E=Sd'+S'e$
$F=Se'+S'f$
$g=[A'(B+C+D)+AB'D'E+BC'DE+B'C(D+E)]$ delayed by β

Note that for $m=6$ the A stage is logically gated and this counter is therefore not a simple shifting counter. The choice of this mechanization simplified the generator circuit g.

Conclusions

By relaxing the restriction that the sequence of addresses follow a true binary sequence, methods have been presented whereby the instructions in a 1-address digital computer may be sequenced at the pulse repetition rate of the machine. The methods offer the advantage of equipment minimization whether a memory-sequenced device or a 2^m stable-state counter is employed. Synthesis of the former mechanism is straightforward regardless of the size of the memory; synthesis of the latter mechanism has not been attempted for counters with more than 64 stable states. In the event that a memory contains more than 64 instructions, cascading of low-order counters is suggested.

Shifting counters are possible with radices other than binary. The implications of using, in a shifting counter, higher radix devices composed of bistable subunits have not been investigated.

Appendix I. Some Properties of Counting Rings

Consider a sequence $a_0, a_1, \ldots, a_n$, of the following type: Given $m\geq 1$

1. $a_i=0$ or 1 for $i=0, 1, \ldots$
2. $a_i=a_{i+2^m}$ for $i=0, 1, \ldots$
3. $a_i, a_{i+1}, \ldots, a_{i+m-1}=a_j, a_{j+1}, \ldots, a_{j+m-1}\rightarrow i\equiv j$ (modulus 2^m)

Only consecutive subsequences of this sequence will be considered: thus by "subsequence" is meant consecutive subsequence.

By items 1, 2, and 3 it is seen that the sequence a_i may be thought of as a cyclic sequence of 2^m 0's and 1's (i.e., the 2^m digits are arranged in a ring) so that no two subsequences of length m are exactly the same. Such a sequence is called a "full counting sequence" or "full counting ring." By a "truncated counting sequence" is meant such a cyclic sequence of $k<2^m$ digits that no two sequences of length m are exactly the same.

Mainly the full counting sequences are of interest. All such sequences have the property that there must be exactly

$$\frac{2^m}{2^k}=2^{m-k} \text{ subsequences of 1's}$$

of length k and 2^{m-k} subsequences of 0's of length k for $1\leq k\leq m$, and no such sequences for $k>m$.

By a maximal subsequence of 1's (or 0's) of length k is meant a subsequence of 1's (0's) of length k which is not a subsequence of another subsequence of 1's (0's) of length $k+1$. With this definition and the foregoing property the following may be proved.

Theorem 1: For a given m, there is a unique function $M(k)$, $k\geq 1$, in which $M(k)$ is the number of maximal subsequences of 1's (0's) of length k in any full counting sequence.

To prove theorem 1 the following lemma are needed:

Lemma 1

$$m+\sum_{j=1}^{m-2} 2^{j-1}(m-j-1)=2^{m-1}$$

for $m\geq 1$ when $\sum_{j=1}^{m-2}=0$

if $m-2<0$

Proof: The lemma holds for $m=1, 2$. Assume it holds for $m=A$:

$$A+\sum_{j=1}^{A-2}2^{j-1}(A-j-1)=2^{A-1}$$

Multiplying by 2 yields

$$2A+\sum_{j=1}^{A-2}2^{j}[A-(j+1)]=2^{A}$$

$$A+1+A-1+\sum_{j=2}^{A-1}2^{j-1}(a-j)=2^{A}$$

$$(A+1)+\sum_{j=1}^{(A+1)-2}2^{j-1}[(A+1)-j-1]=2^{(A+1)-1}$$

By induction, the following assertion results: There is one maximal subsequence of 1's of length m. There are two subsequences of this subsequence of length $m-1$. Thus no more subsequences are needed of 1's of length $m-1$. There are only three subsequences of the m-long subsequence of 1's of length $m-2$.

Continuing in this manner by induction: Assume for $0<k\leqslant s\leqslant m-2$ there are 2^{k-1} maximal subsequences of 1's of length $m-k-1$, no such sequences of length $m-1$, and one of length m.

For a sequence of 1's of length r, there are $r-t+1$ subsequences of 1's of length t, $t\leqq r$. Thus there must be the following number of maximal subsequences of 1's of length $m-s-2$:

$$\frac{2^m}{2^{m-s-2}}-\left\{M+1-(m-s-2)+\sum_{k=1}^{s}2^{k-1}\right.$$

$$\left.[m-k-1+1-(m-s-2)]\right\}$$

$$=2^{s+2}-\left[s+3+\sum_{k=1}^{s}2^{k-1}(s+2-k)\right]$$

$$=2^{s+2}-\left[s+3+\sum_{k=1}^{s}2^{k-1}(s+3-k-1)\right]$$

$$=2^{s}(s+3-s-1-1),\text{ by lemma 1}$$

$$=2^{s}$$

Thus, there are 2^s maximal subsequences of 1's of length $m-(s+1)-1$.

By induction, $M(k)$ uniquely becomes

$$M(k)=\begin{cases}0 & k>m\\ 1 & k=m\\ 0 & k=m-1\\ 2^{m-k-2} & m-2\geqslant k\geqslant 1\end{cases}$$

Similarly, $M(k)$ proves also to be the unique number of maximal subsequences of 0's in any full counting sequence.

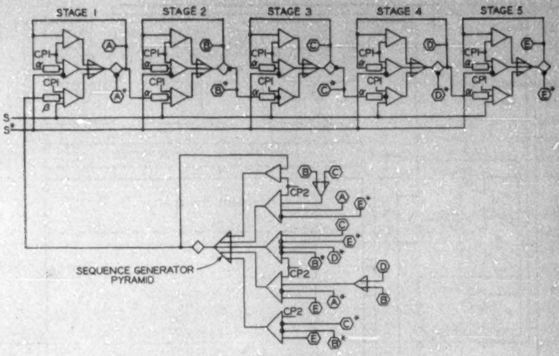

Fig. 6. Gated shifting counter

Appendix II. Alternative Method for Constructing Counting Rings

The following is a method for constructing a cyclic sequence which under certain circumstances is a full counting sequence and otherwise is a truncated counting sequence. (The method has been successful for all values of m tried to date, including $m=12$.) The process is described inductively.

The various m-long subsequences may be thought of as the numbers from 0 to 2^m-1 represented in binary notation.

1. Let the first m digits in the sequence be 1's; in binary notation, the number 2^m-1.

2. Let 0 be the $(m+1)$st digit in the sequence.

3. Suppose one has proceeded through the kth step. If the last digit in the sequence after the kth step (called the "kth step sequence") is an i ($i=0$ or 1), then the $(k+1)$st step consists of adding an i to the sequence, provided:

   a. The number of consecutive i's at the end of the newly formed $(k+1)$th step sequence is r; then $M(r)$ maximal i-sequences of length r have not previously appeared in the sequence, and

   b. The number represented by the last m digits of the $(k+1)$th step sequence has not been represented in such form by any previous subsequence of m digits.

4. If 3*a* or 3*b* is not satisfied, the $(k+1)$st step consists of adding the inverse digit $1-i$ to the kth step sequence provided 3b now holds for the new $(k+1)$th step sequence.

5. If neither of the steps 3 or 4 is possible for the $(k+1)$st step, no new digits are added to the sequence, but rather:

   a. The beginning and end of the kth step sequence of $i=0$ are joined and thus a cyclic sequence is obtained, or

   b. If $i=1$ and r is the number of 1's ending the kth step sequence, the sequence cyclic is made by considering these r 1's as the first r of the initial sequence of m 1's.

The following theorem can be proved but the proof is too long for inclusion here.

Theorem 2: If in using the foregoing procedure the sequence cyclic must be made by method 5a, a full counting sequence is obtained; if method 5b must be used, a truncated counting sequence results. Thus whenever it is no longer feasible to proceed beyond a 0 with the method described in either 3 or 4, a full counting sequence will be obtained; when not beyond a 1, a truncated sequence will result.

An Amplitude-Stabilized Bridged-T Oscillator

KURT ENSLEIN
MEMBER AIEE

IN AN ANALOG computer application which used several nonlinear elements, there arose a need for a sinusoidal oscillator of 2,500 cps (cycles per second) frequency, with frequency stability of better than 0.5%, amplitude stability greater than 0.2%, and a harmonic content of less than 0.2%. There are very few circuits which can reconcile these requirements, one of these being the Meacham oscillator.[1] If the requirement is for an oscillator in the audio-frequency range, the Meacham circuit loses its attractiveness, since quartz crystals in this frequency range are rather cumbersome. If an inductor and a capacitor are substituted for the crystal, it is found that some other circuits have better inherent phase magnification.

The problem of good frequency stability is usually solved concurrently with the problem of good waveform. One of the best circuits from this standpoint is the bridged-T oscillator,[1,2] with the use of the resonant network of Fig. 1. However, the conventional circuit has the inherent weakness that its amplitude stability is a function of the Q of the resonant series circuit. In the audio-frequency range this Q is, for all practical purposes, determined by the inductor. The Q of inductors is not a constant, but varies with temperature. (The effect of a change in Q is to unbalance the network. This changes the feedback factor and hence the oscillation amplitude; see the section "Control Network Characteristics.")

As an illustration of this effect, consider an oscillator with an open loop gain $A=600$. For a reasonable amplitude of oscillation, the closed loop gain $a=2$, which means that the feedback factor $\beta=2/600$ or 0.0033. Let this oscillator use a coil, the Q of which changes by 0.5% when the temperature is changed from 30 to 60 C (degrees centigrade). A change in R of 2% will be required with typical constants to keep the bridge network balanced. It can be shown that in a bridged T with a component of this nature, a change in R of 2% would change β to 0.011. This would approximately triple the output voltage of the oscillator. If β decreased, the oscillator would stop oscillating, since a would become less than 1, or even negative. Then, the need for amplitude stabilizing a bridged-T oscillator obviously is indicated.

Method of Approach

A number of methods[1-3] have been developed in the past for the amplitude stabilization of class A oscillators. These may be divided into two categories: thermistor control and rectified-signal feedback.

The thermistor method, while quite practical, cannot produce stabilization ratios, i.e., $[f(T)$ with compensation$]/[f(T)$ with compensation$]$ greater than about 20, due to inherent limitations in the temperature coefficients of thermistors. The second method may be applied in two ways: either one may control the amplitude of oscillation directly by changing the gain in the oscillator loop, or one may pass the variable oscillator signal through a variable gain amplifier, the latter being controlled by its own rectified output signal. In the first case, only relatively small stabilization ratios can be obtained in single circuits and, in the second case, variable μ tubes inherently also have variable μ for the signal, and therefore introduce harmonic distortion. The same problem exists in the control of an oscillator by changing the μ of all of the tubes in the loop. Still another method uses the frequency-determining network itself to control the positive feedback signal, without at the same time influencing the frequency of resonance, as shown in schematic form in Fig. 2. In this method, the network, in addition to its normal input and output terminals, also has a "control" terminal. When the proper potential is applied to this terminal, the "balance" conditions of the network may be made to change in response to the control potential. Some of the networks that might be used also have the property of phase inversion for the fundamental (oscillation) frequency, and no phase inversion for harmonics. The loop $A_1(\omega)$ can therefore be a positive feedback loop, and can oscillate if its gain ≥ 1.

The output signal is also rectified, and compared to a reference level. The difference between reference and rectified signal is amplified in A_2 and applied to the control terminal of the network in such a sense as to minimize changes in the magnitude of the output voltage. If the control gain of the network and A_2 can be made large enough, it should be possible to obtain any desired degree of amplitude stabilization of such an oscillator.

Control Network Characteristics

References 2, 4, and 5 show that one of the better compromises for a selective network to be used in an oscillator is the bridged T. This network, shown in Fig. 2, has several interesting properties.

First, its frequency response is expressed by

$$A(w)=\frac{1}{1-j\dfrac{\rho}{\rho^2-1}\dfrac{2}{Q_0}} \tag{1}$$

where

$$\rho=\frac{w}{w_0}=\frac{\text{operating frequency}}{\text{null frequency}}$$

For Q of the order of 10, the network has a very small loss at the second and higher harmonics of the fundamental frequency. This means that if the network is used in a negative feedback loop, β approaches unity at the second and higher harmonics, and distortion components are consequently reduced to very small values.

Second, the network can produce zero output under the following conditions:

$$Q_0=w_0 2RC \tag{2}$$

where

$$Q_0=\frac{w_0L}{2}$$

and

$$w_0^2=\frac{2}{LC} \tag{3}$$

An analysis to determine the response of the network at w_0 as R is changed

Paper 57-76, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 21–25, 1957. Manuscript submitted July 16, 1956; made available for printing August 15, 1957.

Kurt Enslein, formerly with the University of Rochester, Rochester, N. Y., is now with Brooks Research, Inc., Rochester, N. Y.

The original suggestion of W. F. Coombs, Jr., to use the bridged-T oscillator for the low distortion requirement should be acknowledged, as well as the untiring efforts of Anthony Formicola in building, improving, and "trouble-shooting" the circuit and making all measurements reported in this paper. The work was supported by the Atomic Energy Commission.

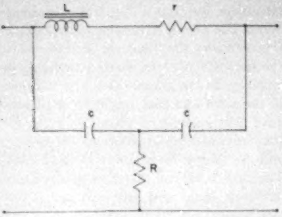

Fig. 1. Bridged-T network

from the value required for balance shows that for $R > R_0$, where R_0 = resistance required to balance the network, the network produces an output voltage proportional to the change in R, with the same phase as the input voltage. If $R < R_0$, the output is still proportional to the change in R, but the output voltage is now 180 degrees out of phase with the input voltage. All this is accomplished without influencing the response of the network at the harmonics.

In the oscillator of Fig. 2, it is then possible, by making R slightly larger than R_0, to use a bridged-T network for both positive and negative feedback, without prejudicing the frequency stability of the network in any way, or increasing the attenuation of the network at harmonics of the oscillator frequency.

Third, a change in Q, which is equivalent to a change in r, may be compensated by a corresponding change in R, without affecting the resonance frequency. There is, however, a slight change in phase shift with frequency, due to the basic change in Q. This will result in a very slight change in oscillation frequency. The salient fact, however, is that, by adjusting R, the attenuation of the network may be kept constant as Q is changed.

This latter characteristic is of fundamental importance when temperature changes are considered. The temperature changes are almost always accompanied by variations in Q, and therefore can cause changes in the amplitude of oscillation of the system.

It is then evident that, if a variable resistor is substituted for R, a means for keeping the oscillator amplitude constant has been obtained. Such a resistor[8] is the dynamic plate resistance of a vacuum tube. If the proper tube is chosen, and operated in a region where it exhibits a large slope of plate resistance versus plate current, it is conceivable that the network might have some control gain greater than one.

The Network

CHOICE OF INDUCTOR

The oscillator in question is intended to operate at 2.5 kc, over a temperature range of 30 to 60 C. From the standpoint of frequency stability and waveform purity, a high Q is desired, preferably greater than 10. At the frequency in question, in order to reduce the coil to a reasonable size, a fairly high-permeability (μ) core is desirable. However, in general, the higher the μ of the core (due to its lower Curie temperature), the higher the change in μ with temperature, and therefore the greater the change in response of the network with temperature. Also, when the Q is high enough, a major part of the losses reside in the resistance of the wire. The resistance also changes with temperature and may be compensated to a fair degree by means of thermistors.

Table I shows temperature coefficients for two typical inductors that are usable in the oscillator in question. Both have a nominal inductance of 2.5 henrys at 1 kc. It may be seen that the temperature coefficient of inductance of the two units is not materially different, but the temperature coefficient of Q (as indicated by the required change in R to rebalance the network) is much greater for the type *MQA-14*. This latter inductor has a Q of the order of 90 at 2.5 kc, whereas *MQL-1* has a Q of only 6.35. Since a reasonably low distortion level may be obtained with a Q of 6.35, and since amplitude stability is such an important consideration in this case, the *MQL-1* unit was chosen. The particular sample used had an inductance of 2.92 henrys at 2.5 kc. Practically all the losses were due to the core, which probably accounts for the smaller temperature coefficient of Q.

With the hindsight possible after the completion of this project, it is not very clear whether the choice of the low-Q coil was a wise decision. While the high-Q coil has a higher temperature coefficient of Q, it seems plausible that it would have been possible to increase the loop gain to make up for this larger variation. This is especially so in view of the methods of obtaining R, described in a later section. The use of a higher-Q coil would of course have entailed a lower harmonic distortion.

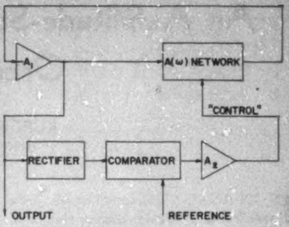

Fig. 2. Block diagram of system

GAIN

Fig. 3 shows a computed gain characteristic for a bridged-T network with components somewhat different from the ones used in this application. It will be noted that the phase reversal mentioned earlier occurs. In the network used for this application, the measured control gain is approximately 60.

CHOICE OF CONTROL TUBE CIRCUIT

Several conflicting requirements are imposed on the control tube. On the one hand, the circuit requires a dynamic plate resistance of approximately 70 kilohms; on the other hand, its d-c resistance should be rather high, so as to permit the use of a large series-dropping resistor. This resistor will be in parallel with the dynamic resistance of the tube, and should therefore be large, in order not to reduce the gain of the system appreciably. Also, one would like to obtain as large a change in plate resistance with grid voltage as possible; yet there should be no appreciable nonlinearity of plate resistance versus plate voltage over the desired operating region.

This latter point probably requires explanation. When a resistor is used as R in the bridged-T network, no consideration need be given to its voltage character-

Table I. Temperature Characteristics of Two Inductors

Inductor	T, Degrees Fahrenheit	$\Delta I\%$	$\Delta I\%$, Degrees Fahrenheit	$\Delta R\%$	$\Delta R\%$, Degrees Fahrenheit
MQL-1	79				
	125	−0.56	−0.12	+1.66	+0.036
	150	−0.72	−0.010	+3.04	+0.043
MQA-14	79				
	125	−0.500	−0.011	−10.05	−0.218
	150	−1.35	−0.019	−17.5	−0.246

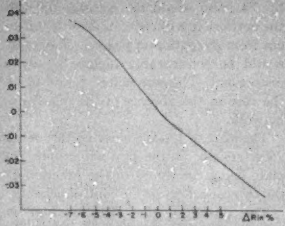

Fig. 3. Computed input-output characteristic of bridged-T network

istic, since the resistor is usually far more linear than the other components in the bridged T. However, when the dynamic plate resistance of a triode is substituted, the possibility exists that plate resistance versus plate voltage is a nonlinear function. Since half the oscillator signal appears across R, the control tube plate resistance should vary linearly when its plate voltage is changed by half the oscillator output voltage. In this particular case, the desired output of the oscillator is 10 volts, peak to peak. The incremental voltage range of interest for plate resistance linearity is then 5 volts.

The question now arises as to what type of tube should be used. Since the requirement is for dynamic plate resistance of approximately 70 kilohms, a triode is clearly indicated. Then the question becomes whether one should use a low μ or a high μ triode. Reference 7 shows that the μ of a triode is quite independent of plate potential, but that gm varies as

$$(E_g - E_{p/\mu})^{1/2} \tag{4}$$

Since $R_p = \mu/gm$, plate resistance will vary with plate voltage unless some precautions are taken. The most obvious solution is to use a small plate voltage and a high-μ tube, so that the second term in equation 4 is minimized. This process is limited by the minimum plate voltage that may be used on a given tube before excessive grid current is obtained so that, by and large, the second term of the equation is usually approximately equal to the first term. However, the effectiveness of the grid in screening the anode-grid space from the cathode-grid space is usually better in high-μ triodes. Therefore one may expect fewer nonlinearities to be encountered with a high-μ triode than with a lower μ tube.

A second method would consist of keeping the second term in equation 4 constant, by choosing a tube for which μ changes linearly with E_p. This is basically a very difficult method, and does not represent a practical approach unless a special tube were to be constructed for the purpose.

A third method consists of introducing a cathode resistor. The effective plate resistance of a triode with a resistor in the cathode to ground lead is

$$R_p \text{ eff} = R_p + (\mu + 1)R_k \tag{5}$$

The second term in equation 5 may be made dominant, which in turn makes the second term in equation 4 less important. The only problem for this particular design is that of obtaining 70 kilohms. For the second term of equation 5 to be dominant, it must represent most of this 70 kilohms, and therefore R_p must be rather small. This implies either rather high-current operation of the triode, or a basically low R_p tube, which usually also means low μ.

Unfortunately, for the value of $R_{p\ eff}$ desired, an improvement in linearity of only approximately 2.5 times may be obtained with presently available tubes. Due to the cathode resistor, the gain of the control tube is necessarily less, since the cathode resistor causes a form of degeneration. On the other hand, the scheme of Fig. 4 may be used to dispose of the problem. In this method of operation, $R_{p\ eff}$ is varied by changing R_k, which change is accomplished by changing the transconductance of V_2. While it might be surmised that this circuit is compensated for filament potential changes, much as a differential d-c amplifier, this is not entirely the case, since the compensation is effected by virtue of a change in R_p. With typical tubes, the control gain $[(dR_{p\ eff})]/(dE_{g2})$ is of the order of 20 kilohms per volt, whereas a simple triode such as a *12AX7*, can produce changes of 70 kilohms per volt.

Tests of various tubes (*12AX7*, *12AU7*, *5965*, *6J6*, *6463*) reveal that the best compromise of linearity and slope for this design may be obtained with the *12AX7* operating at approximately 0.5 milliampere, and at least a 100-volt plate-to-cathode potential.

There remains one consideration in the choice of the tube type, if the oscillator is to be used at moderately high frequencies. Due to the Miller effect in the control triode, it is possible to obtain unstable operation if enough oscillator signal is allowed to appear at the grid of the triode. The remedy for this difficulty is to make the impedance in the grid low enough at the oscillator frequency. This has been accomplished by means of a by-pass capacitor from grid to ground.

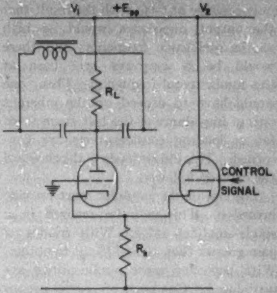

Fig. 4. Variable R circuit

The A-C Loop

The oscillator loop for this design should have several characteristics which are easily defined. It should have high gain, in order that the harmonics will be largely fed back. Yet inherent harmonic distortion should be low, so that the negative feedback of the harmonics need not work against too severe odds. The output tube should operate at such a level that it can deliver 10 volts peak-to-peak into an impedance of 10,000 ohms. This means a fairly high-level output stage.

Finally, the loop phase shift, excluding the frequency-determining network, should be 180 degrees and should vary very little with frequency near the oscillation frequency. In this case, this means that coupling and by-pass time constants should have a period long compared to 400 μseconds. Actually, in order to reduce the effects of stray 60 and 120 cps (introduced by filaments, etc.), it is desirable that the open loop gain be high at these low frequencies, so that essentially unity negative feedback will be available for these components.

Referring to Fig. 5, the a-c loop consists of the network described in the previous section, V_1 and V_2. This particular circuit was arrived at from the following considerations: 1. The *6Y6-G* was chosen as a cathode follower to give low output impedance and because of its relatively low μ. This latter feature gives a long grid base, which in turn means that the signal swings over a minute fraction of it. While the cathode-follower action effectively increases the base, lower power or higher μ tubes still produced distortion too high to be tolerated here. While an anode follower[8] would do as well (except for at least three times the output impedance), a simple amplifier would not, as there would be negative feedback at $f \neq f_0$, but only positive at $f = f_0$, with the result that the output impedance would be high at the oscillation frequency, and there would be a narrower grid base at the fundamental frequency. Then, one would have to depend on the inherent output impedance of the last stage in so far as loading considerations are concerned. This clearly leads to the choice of the cathode follower.

The rest of the amplifier must provide inversion. This may be realized in a single-amplifier stage. With triodes, a gain greater than 70 is difficult to obtain. With pentodes, more nonlinearities are introduced. One may, of course, use an odd number of stages greater than 1, but the complications, cumulative distortion, etc., become rather cumbersome.

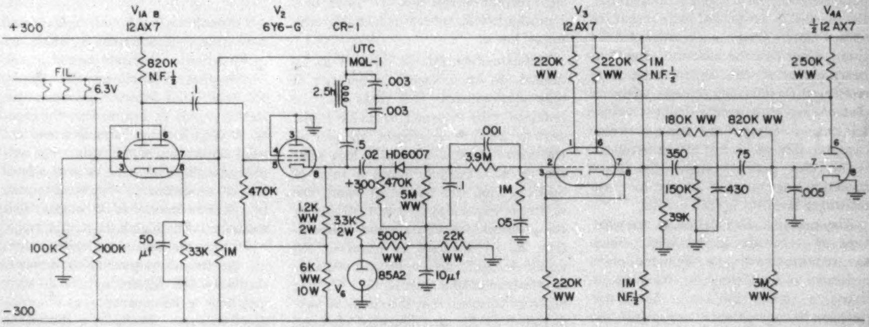

Fig. 5. Over-all circuit

As a compromise, the cascode circuit is then chosen. This gives a gain of approximately 700, without substantial nonlinearities. The cascode is very much in need of a high impedance load, due to its very high output impedance. This is another good reason for the choice of the cathode follower output stage.

The Control Loop

The control loop, Fig. 5, includes, besides the control network and the a-c loop, V_3 and V_4 and *CR-1; CR-1* is a Hughes Aircraft Company silicon junction diode, which serves the purpose of peak-rectifying the oscillator output. This diode was chosen in preference to a vacuum diode because of its lack of filament. Since its back resistance compares favorably with a vacuum diode, no loss in rectification efficiency has been incurred, except perhaps for the high knee of the silicon diode. The lack of filament eliminates any problems of 60- and 120-cps modulation at this stage, and also circumvents the variability of filament potential, which would have the effect of introducing an error at the input of the system, and therefore affect the output amplitude.

The output from the diode is bucked against a fixed d-c voltage derived from a gaseous discharge tube of good temperature stability. (A Zener diode is another good possibility.) The resultant voltage is applied, through a stabilizing network, to the grid of $V3_a$, which is one tube of a differential amplifier, with a gain of the order of 30. The other side, $V3_b$, has impressed on its grid a voltage which is proportional to the difference between the positive and negative power supplies. This connection has the effect of compensating for changes in the supply potentials, in order to permit the use of less well regulated power supplies. Later data will demonstrate the effectiveness of this arrangement. The differential amplifier is used in preference to a single triode in order to obtain compensation for filament potential changes. These filament potential changes, if not compensated, would have the effect of introducing a spurious input voltage to the amplifier, and therefore would appear as an error signal, even when no error exists.

The output of $V3_b$ is coupled to a parallel-T network, tuned to the oscillation frequency. The output of the network is coupled through a d-c divider to the control tube $V4_a$.

The null filter is needed to reduce the oscillation frequency component on the grid of the control tube, for oscillation voltage at this point would be amplified by $V4_a$, and would be reintroduced into the network in a phase considerably different from the optimum phase. The result would be considerably higher harmonic distortion. This was indeed found to be the case in the absence of the parallel-T network.

The plate of $V4_a$ is connected through a *250K* resistor to the positive supply, its plate being connected to the junction of the two capacitors in the control network.

The choice of the *250K* resistor is influenced by two considerations: its value should be large compared to the plate resistance of the control tube so that it does not shunt it appreciably, and its value should also be such that, with the current required through the control tube to establish the proper resistance, it does not reduce the plate voltage to a value so low that appreciable grid current will flow.

Since about 0.5 milliampere flows through the control tube, the plate voltage here proves to be 175 volts, and the ratio of the plate resistor to the plate resistance is about 3.5 to 1. This seems a reasonable compromise.

The point that the plate resistor should not appreciably shunt the control tube is debatable, for if a smaller value is used the control tube must work in a higher plate resistance region, and it is entirely possible that in this region, the over-all control gain may actually be higher. There is also the possible advantage that since most of the resistance would be ohmic, nonlinearities in the plate resistance characteristic would be less likely to affect the linearity of the oscillator. This aspect of the problem has not been thoroughly investigated.

Performance

Frequency Stability Versus Temperature

The frequency stability was measured with temperature as a variable. The range of measurement was from 24 to 66 C in all these tests. From the data in Table I, one would expect a maximum frequency change of 0.38%. However, in the actual circuit, the peak-to-peak deviation of frequency was 0.62%, the average deviation less than 0.05%. Most of the large deviations occurred during the warm-up period, and are probably due to the heating of the wire in the coil. The core, having a much longer time constant, did not heat as rapidly. That the average change is less than expected must be attributed to a fortunate choice of other frequency-determining components (the two capacitors in the bridge). Also, the amplitude stabilization of this circuit operates by virtue of a slight phase shift, which in this case is in a direction such as to aid the frequency stability.

Frequency Stability Versus Supply Voltage Changes

Changing the supply voltage by ±3.3% produced an undetectable change in frequency. The level of detection here is one part in 2,500.

Distortion

At a 10-volt peak-to-peak output, the second harmonic content was 0.08% and the third was 0.02%; further harmonics were negligible compared to the first three. Total harmonic distortion was therefore of the order of 0.1%.

Amplitude Stability Versus Temperature

Using the same range of temperature variation as for the frequency stability measurement, the peak-to-peak amplitude variation was 0.5%. After the coil had stabilized at the new temperature, the deviation could not be measured, which means that it was less than 0.02%.

Amplitude Stability Versus Supply Voltage Variations

Before the network in the grid of $V3$, was inserted, a 3.3% change in one of the supply potentials produced a 5% to 6% change in output level. After the network was inserted, a −3.3% change in the positive supply changed the output by −0.25% and a −3.3% change in the negative supply caused a −0.16% change in the output. If both supplies are then varied simultaneously, which is usual for line voltage fluctuations, the net change for a 3.3% change in supply voltages will be −0.09%.

The filament voltage on all tubes was changed by ±10%. The observed effect on the output is a change of less than 0.1%.

Other Possible Applications

Due to the amplitude-regulating characteristics of this oscillator, a number of other uses suggest themselves. For example, it would seem very logical to use the oscillator as an amplitude-modulated device, of very low distortion. For example, this can easily be done by superimposing an a-c signal on the d-c signal on the grid of the control tube.

It is also possible to substitute a saturable reactor for the coil used here, in order to provide a frequency-modulated oscillator. In this case, since such reactors usually change in Q along with inductance, due to the variable saturation of the core, and since a change in frequency will mean a required change in R, the circuit would tend to keep the amplitude stable independently of frequency, and without affecting the harmonic distortion content. In short, this approach is applicable to cases where, for one reason or another, the output amplitude of an oscillator changes in response to various disturbances, and where it is desired to keep the amplitude of the oscillator constant.

New Printing Demand Meter

P. V. TERRY
NONMEMBER AIEE

Synopsis: A new printing demand meter has been designed. Several innovations have resulted in a device which has higher accuracy, lower cost, and smaller size than previous printing demand meters. Some of the novel features of the new improved design are discussed.

THREE TIMES the amount of electric energy was sold in 1957 as in 1947. Electric energy usage will almost triple again by 1970. These figures[1] are indicative of the rapid development of the electrical industry. It is growing at a far greater rate than the total population or the number of electric energy users.

Likewise, in the metering of kilowatt demand the energy used during the demand intervals has been increasing. On large connected loads where an impulse-operated printing demand meter is used to obtain a permanent demand record, each impulse can represent an extremely large number of kilowatts which in some cases may be considered excessive for good metering practice. A printing demand meter capable of accepting an increased number of impulses per demand interval became necessary to reduce the kilowatt value of each impulse. Impulses which up to now had been lost during the print and reset operation of the demand meter are important and should be recorded to improve the accuracy of demand measurement and customer billing.

The new printing demand meter described in this paper was designed to provide the needed long-life meter which could more accurately measure and permanently record electrical demand information; see Fig. 1. Accuracy compatible to that of the watt-hour meter, which acts as the primary sensing device and impulse generator for the printing demand meter, is a design feature of the new printing demand meter.

The purpose of this paper will be to describe some of the unique design approaches which were employed to result in a more accurate, compact, and lower cost printing demand meter. The portions of the over-all design to be discussed are: 1. The printing mechanism. 2. The record paper. 3. The impulse accumulator and governor. 4. The reset mechanism for the running demand indicator.

The Printing Mechanism

In the past, printing has generally been accomplished by utilizing a solenoid to accelerate a printing arm and platen. The kinetic energy, which the solenoid transmitted to the printing arm, was used to obtain a printed record on a paper tape by impact of the platen with carbon tape over record tape over the raised numerals on the counting wheels. A variation in the clarity and density of the record occurs when this system is used since the pull-in speed of the solenoid is a function of voltage which may vary up to 10% in some locations. The pull-in speed also depends upon the portion of the cycle in which energization occurs. To overcome this difficulty, a spring-driven platen arm actuated by a motor-driven cam is used to provide constant printing arm energy resulting in uniform printing density and clarity; see Fig. 2.

In the past, the necessary adjustments to line up the face of the platen with the numeral faces have been provided. By using a frictionally restrained ball joint to secure the platen to the printing arm, the assembly becomes self-adjusting. A further advantage is gained with this construction because of the ease with which an old platen may be snapped out and replaced with a new one without need for tools.

The Record Paper

The usual means of obtaining a printed record has been to use a carbon tape or a typewriter ribbon in conjunction with a record paper tape. The image of the counter numerals is imparted on the record tape when struck by a platen. The new design eliminates the carbon tape, spools, guides, and driving mechanism which have been necessary in the past. The elimination of these parts is made possible by having a single record tape specially coated to provide a surface which may be permanently marked by pressure against the coating. Fig. 3 illustrates the construction of the record paper. A layer of white paper is coated with black or other suitable dark color. This is then coated with a spongy whitish layer. Where the spongy layer is compressed or physically removed, the dark coating will show. The action of the platen on the paper when it strikes the counter figures causes the dark undercoating to show, duplicating on the record paper the figures of the counter at the instant of impact.

A further advantage of the specially coated record paper over the combination carbon or typewriter ribbon and record paper is that legible records are obtained over a greater temperature range. The new record tape can actually be used at −40 C (degrees centigrade) and up to 100 C. Heaters have been necessary in previous designs to keep the carbon tape usable at below freezing temperatures. Also, at temperatures over 60 C, the wax on carbon tape would melt and soon fail to produce a record.

The Impulse Accumulator and Governor

To obtain a maximum impulse count of 999 instead of the previous 299, a 3-figure resettable counter is used. Since between 1 and 2 seconds are required to print and then reset the printing counter, it was possible that one or two impulses from a watt-hour meter or other sensing device might be received during this interval. This could cause smeared printing if the counter figures were advancing at the same time that printing occurred, or an impulse would be lost completely if it should come in after printing occurred but before the counter had been completely reset. These difficulties have been overcome by a means of locking the counter drive shaft and a means of storing, then counting, any impulse which entered the meter while the counter driving gear was locked. To lock the counter drive shaft during printing and resetting, a locking cam is made to rotate to a position of interference with a pin in the driving gear of the counter. Since, with the locking cam in this position, the counter drive gear cannot rotate during reset, the gear meshed with it cannot rotate; see Fig. 2.

At this time the features of the accumulator will be discussed so that its relationship to the counter during and just after the completion of reset may be better understood. Fig. 4 shows the accumulator assembly, which consists of a shaft, and impulse motor-driven gear secured to the shaft; and a second gear loose on the shaft but held in position

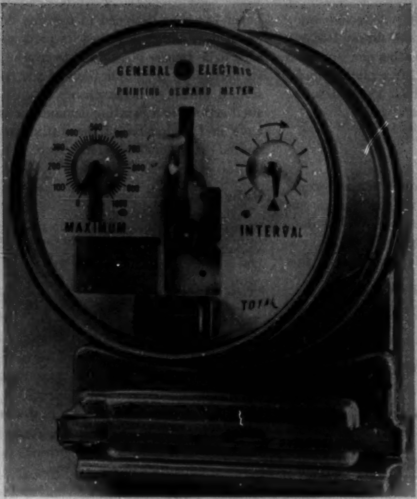

Fig. 1. New printing demand meter

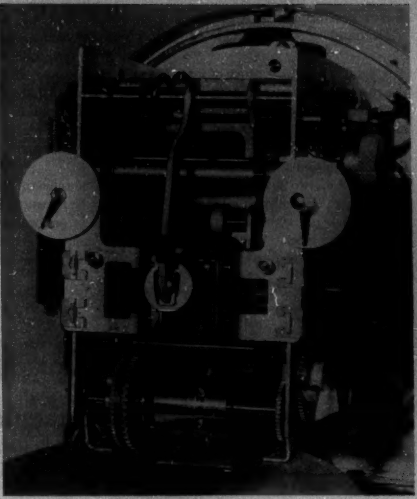

Fig. 2. Front view of new printing demand meter: faceplate down

relative to the first gear by means of a helical spring. A pin on each of the gears extends to overlap the other and prevent more than one revolution of relative motion between the two gears.

The two pins are biased together by the spring. The second gear rotates with the motor-driven gear and drives the printing counter except when the counter drive gear is locked. In this condition, the motor driven gear will rotate with each incoming impulse and cause the spring to wind up. At the completion of reset, the locking cam moves out of the way of the pin on the counter drive gear. If any impulses have been received during the reset period, the accumulator spring will unwind rotating the counter drive gear until the stop pins on the two accumulator gears meet. Any impulses received during reset are in this way registered on the printing counter.

It was found that the action on the spring unwinding was too fast to obtain proper life or registration of the impulses on the printing counter, and a way to slow this action was needed. Three standard methods of governing the speed of such an action were: 1. An air governor or fan, 2. an eddy current disk, and 3. a flyball or other centrifugal and frictional device.

All three of these methods were unsatisfactory because they would have to operate during each count or else use some sort of a differential to make the governor operate only if impulses are received during reset.

The method finally evolved consists of a ratchet wheel fastened to one of the accumulator gears and a rocking arm escapement mounted on the second accumulator gear. The inertial forces resulting as the weighted rocking arm escapement is caused to oscillate by the ratchet wheel keeps the speed of the spring-driven gear within bounds. The governor operates only when necessary after the completion of reset and no complicated differential gear trains are required. With this design, wear of the governor is not a problem.

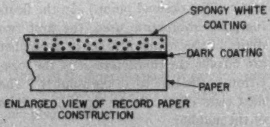

Fig. 3. Record paper construction

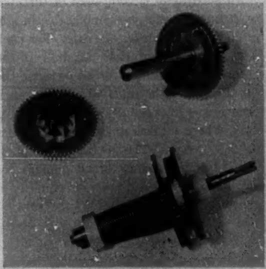

Fig. 4. Accumulator and governor

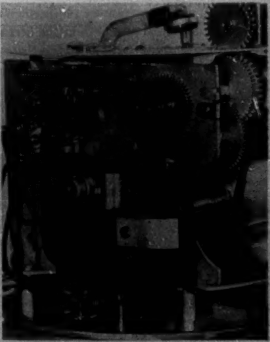

Fig. 5. Demand dial reset mechanism

Reset Mechanism of Running Demand

A detail which may prove of interest to the reader is the rack rod drive associated with the running demand, which is shown in Fig. 5. In an early design stage, two sets of bevel gears were employed to obtain a translation and rotation of the axis of rotation of two shafts. The same job is done more efficiently at a lower cost by using a rack rod which reciprocates in a nylon bearing block. The rack rod, as its name suggests, is a rod with annular rack teeth cut on it. A reciprocating pinion meshes with, and drives, one end of the rack rod. The other end transmits reciprocating motion to a pinion on the demand dial shaft which acts to reset to zero the running demand dial.

Conclusions

The value of a printing demand meter may be measured by the cost which it entails in performing its required function. To increase its design value, the new printing demand meter described in this paper has been designed to measure demand more accurately than its predecessors, to be smaller in size, and to cost less. In particular, the application of the described means of accomplishing the desired actions in a printing demand meter have in the opinion of the author advanced the art of demand metering.

The Use of a Digital Computer in a Generator Reserve Requirement Study

HOMER E. BROWN
MEMBER AIEE

A MODERATE-SIZED digital computer can be an effective tool in the calculation of the probability of simultaneous forced outages which are used in determining the generator reserve requirements of a utility system. The large amount of arithmetical work connected with an extensive study by the probability method makes the use of a digital computer imperative if the results are to be obtained in a reasonable length of time. This paper describes a program for the International Business Machines (IBM) *650* digital computer that has been written for this purpose.

The calculation of the probability of simultaneous forced outages used in determining generator reserve requirements has been discussed at length in the literature.[1–8] Reference 1 discusses the theory and reference 2 the application of the method of probability in determining generator reserve requirements as developed by Adler. In the following a program is described for the IBM *650* that was written specifically for this procedure of calculation. References 3 through 8 provide background for the subject but are not referred to directly.

The result of the probability calculations is a curve showing the relationship between forced outages in megawatts and the interval between such occurrences. The curve indicates the generator reserve that must be provided for the forced outage contingency to ensure the desired system reliability. Provisions for overhaul schedules and other factors must be determined in a separate calculation.

In Adler's method, a system is subdivided into subsystems in order to increase the accuracy of the results without an excessive amount of computation. Each subsystem is composed of turbines or generators that are comparable in size and have the same outage rate. For each subsystem, computations are made of the capacity lost through forced outages, the duration, and the interval between such occurrences for r simultaneous forced outages, where r takes on successive values $0,1,2,\ldots, r_{max}$. The maximum number, r_{max}, of simultaneous forced outages for small subsystems is usually set equal to n, the number of machines in the subsystem. In larger subsystems r_{max} is assigned a value large enough for the interval between such simultaneous occurrences to be several orders of magnitude greater than the desired reliability, decided upon by management. This facilitates the drawing of the forced outages in megawatts versus interval curves.

To obtain the probability, duration, etc., for the entire system it is necessary to combine the values for the various subsystems until the system has been reassembled. After each combining operation, the results must be grouped (condensed) before combining with another subsystem. This process is repeated over and over until the system is complete.

The final curve of forced outage in megawatts versus interval for the entire system permits management to decide upon the amount of reserve capacity necessary to protect the system against forced outages to the degree dictated by company policy.

Computations of forced outages are based upon the duration and interval between such outages for the different types of equipment as obtained from national averages and records of the system with which the author is connected. The results of these computations are the probability, duration, interval, frequency, capacity, and the standard deviation of the capacity for the various amounts of outage.

Discussion of Program

Because the decimal point swings through such a wide range, scaling is impossible. The calculations are therefore made in the floating decimal point mode. (In this mode the computer itself keeps track of the decimal point.) In the floating-point subroutine used, the first two digits in the representation of a number are 50 plus the characteristic of the logarithm, to the base 10, of the number. The next eight digits are the significant digits of the number.

Thus, 1229 is represented as 5312290000 and 0.001229 is represented by 471229-

Fig. 2. Partial print-out of results of part 1, part 2, part 3, part 4, and part 5 of the program

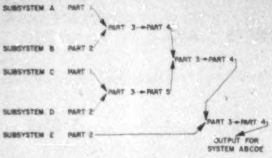
0000. Fig. 1 shows exhibit 1 which is a print-out of data cards and the interpretation of the floating-point representation. Fig. 2 shows exhibits 2 through 6 which are also in this form.

In the calculations of probability by Adler's method no special techniques are required. It is merely the volume of arithmetic that justified the use of a digital computer.

The calculations naturally divides itself into five parts and the program has been written in five subprograms in such a way that any part may be used separately or in combination with other parts, which greatly increases the flexibility of the program. The five parts are as follows:

1. Calculation of the probability of outage of one subsystem.

2. Calculation of the probability of a second subsystem.



SUBSYSTEM A PART 1

OUTPUT FOR SYSTEM ABCDE

NOTE: PART 3 MESHES RESULTS OF 1 & 2, OR 4 & 5, OR 1 & 5, OR 2 & 4.

Fig. 3. Flow diagram showing procedure of solving a problem involving five subsystems

3. Meshing the results of parts 1 and 2 to obtain the probability of outage considering both subsystems simultaneously.
4. Grouping (condensing) the results of part 3.
5. Grouping (condensing) the results of part 3 into a different memory location. (This is necessary so that the outputs of part 4 and 5 can become the input to part 3 in later phases of the study.) See Fig. 3.

In a probability study a set of machines of comparable size and type may be described by seven parameters, as follows:

1. p = the probability of forced outage
2. n = the number of machines
3. mw = average size, megawatts
4. t = the duration of forced outage
5. σ = standard deviation
6. r = maximum number of simultaneous outages to be considered
7. T = interval between outages

Note: T is not independent of t and p.

Details of the Program

From the national averages and system records t (the duration) and T (the interval between outages) for the particular equipment are obtained. This defines p, the probability of outage because $p = t/T$. Then, according to the theory developed, the probability, duration, interval between, etc., for r forced outages of n pieces of equipment to occur simultaneously may be computed.[1,2]

Parts 1 and 2 of the program perform the calculations given in Table I.

These values are stored in consecutive memory locations for the different values of r. When the results are punched out by a 7-word-per-card subroutine, each card contains the complete story for the particular outage of the subsystem. The listed results for two subsystems are shown in exhibits 2 and 3 in Fig. 2.

Part 3 performs the following calculations:

1. $p_{ab} = p_a \times p_b$
2. $t_{ab} = \dfrac{(t_a \times t_b)}{(t_a + t_b)}$
3. $T_{ab} = \dfrac{t_{ab}}{p_{ab}}$
4. $f_{ab} = \dfrac{1}{T_{ab}}$
5. $mw_{ab} = mw_a + mw_b$
6. $\sigma_{ab} = \sqrt{\sigma_a^2 + \sigma_b^2}$

Fig. 4. Flow diagram of program parts 1, 2, and 3

In these calculations, a runs the entire gamut from 0 to r_1 for the first subsystem for each value b from 0 to r_2 for the second subsystem; see Fig. 4 for details of the program.

The probability values obtained from this meshing operation form the p-matrix. The value p_{ab} is the result of meshing p_a of the first subsystem and p_b of the second system, and occupies the position in row a, column b of the matrix. The same is true of the results obtained for t, T, f, mw, and σ. The program is simultaneously computing the elements of six matrices. For two subsystems in which r is permitted to vary from 0 to 30, 900 elements would be produced for each of the six quantities. For each combination of a and b one card is punched which contains the complete information on this particular combination of outages (a outages in the first subsystem, and b in the second). These cards become the input cards for parts 4 and 5, and are therefore punched out in load card format, i.e., a plus punch is emitted in column 1. These output cards are sorted according to magnitude of mw by a card sorter before entering parts 4 or 5 as data. The results are grouped (condensed) into blocks according to the magnitude of mw. Data Cards for this program are non zero output Cards of Part 3 sorted according to mw.

Part 5 program is the same as this part except 1300 addresses become 0700.

Fig. 5. Flow diagram of program part 4 or part 5

size of the blocks is controlled by the investigator. The calculations performed by parts 4 and 5 follow:

1. $p_{a'} = \Sigma p_{ab}$
2. $mw_{a'} = (\Sigma p_{ab} \times mw_{ab})/\Sigma p_{ab}$
3. $\sigma_{a'} = (\Sigma p_{ab} \times \sigma_{ab})/\Sigma p_{ab}$
4. $f_{a'} = \Sigma f_{ab}$
5. $T_{a'} = 1/f_{a'}$
6. $t_{a'} = T_{a'} \times p_{a'}$

In all these summations, $(a'\text{-}1)\ mw_g < mw_{ab} < a' \times mw_g$, where mw_g is the magnitude of the grouping *mw*'s. The output cards of part 3 are read and included in the summations until the next value of *mw*'s excedes the limit for the particular block. The calculations for this group are then completed and the program advances to the next group. This continues until the data are exhausted; see Fig. 5 for details of the program.

Parts 1 and 2 are identical except for the memory block assigned to them for storage of their results. The same is true of parts 4 and 5. Parts 1 and 4 use the same memory block (1300–1899). Parts 2 and 5 use the same memory (700–1299). Part 3 meshes the results it finds in the locations 0700–1299 and 1300–1899 regardless of their origin (original calculations of parts 1 and 2 or grouping operation of parts 4 and 5).

The flow diagram illustrates the method of using this program for a system with five subsystems; see Fig. 3.

Table I

No.	Calculation	Explanation
1	r takes on successive values 0,1,2	
2	$p_r = \frac{n!}{r!(n-r)!}(1-p)^{n-r} \times p^r$	Probability that r of n machines with probability of outage rate p would fail simultaneously.
3	$t_r = \frac{T \times (1-p)p}{p(n-r) + r(1-p)}$	Duration of such simulteanous occurrences.
4	$T_r = \frac{t_r}{p_r}$	Interval between such occurrences.
5	$f_r = \frac{1}{T_r}$	Frequency.
6	$mw_r = r \times mw$	Capacity of equipment involved, megawatts.
7	$\sigma_r = \sqrt{r} \times \sigma$	Standard deviation of capacity, measure of uncertainty.

Recapitulation

If the theory of probability is accepted for determining the amount of generator reserve requirement, this program can obtain the results quickly with a great economy of engineering time. In an extensive study 100 man-weeks of hand calculation were produced in 8 hours on the *IBM 650*. The program has been used several times with excellent results.

The use of the computer relieves the engineer of the drudgery of such a study so that he may spend more time on the technical aspects of the work. The division of the program into five parts greatly increases the versatility of the program.

Synopsis: Wide-band O/H (over-the-horizon) radio equipment in the 680- to 900-mc (megacycle) band suitable for use in toll-quality multichannel telephone or TV (television) circuits is described. The system comprises 60-foot parabolic antennas fed with dual polarization horns, 10-watt drivers, 10-kw amplifiers using 6-cavity klystrons, and receivers which permit dual or quadruple diversity by combining the received signals at the IF (intermediate frequency). The over-all 1-db (decibel) bandwidth is 15 mc, and the time delay distortion characteristics are suitable for interconnection with existing toll-quality radio links.

THE BROAD-BAND tropospheric communication system described can transmit between 120 and 600 telephone channels with trunk circuit quality, or a TV program, up to at least 200 miles. The equipment also interconnects with common carrier telephone networks.

For the 185-mile link between Florida and Cuba, with a path loss of 197 db, this equipment, employing space diversity, was expected to provide a mean carrier-to-noise ratio of about 42 db and a received-signal level above the FM (frequency modulation) threshold at least 99.9% of the time. With 120 telephone channels using frequency division multiplex, the noise on each channel was expected to be less than 26 decibels adjusted at the −9 dbm (decibels below 1 milliwatt) point 99.9% of the time. Actual measurements which were made showed the channel noise level to be about 22 decibels adjusted at zero level. There were definite indications that the terminal equipment rather than the tropospheric scatter equipment contributed largely to the channel noise.

Quadruple diversity, improving performance by about 3 db, may be obtained by combining space and frequency diversity. This combination is possible if an active stand-by system is operated on separate carrier frequencies. The system may also be used as two dual-diversity systems, permitting preventive maintenance on one system while the other is in service. It is also possible to transmit messages and TV simultaneously, each on a dual-diversity reception basis.

This O/H equipment is terminated at the 70-mc IF at which frequency the diversity combining takes place. It is thus possible to connect to either line-of-sight or O/H repeaters at IF instead of base-band frequency. Table I lists the specifications for the system, and Fig. 1 shows its major elements and the switching facility provided.

The first application of this broad-band equipment is the microwave communication system between Miami and Havana jointly sponsored by The American Telephone and Telegraph Company and the International Telephone and Telegraph Company. The system includes two *TD-2* line-of-sight hops in Florida between Miami and Florida City where it connects with the O/H hop to Guanabo, Cuba. A *TD-2* line-of-sight hop completes the system from Guanabo to Havana. This system supplements the present cable system between Florida and Havana to provide many more message channels. It also provides a TV channel between the United States and Cuba.

Converter-Amplifier

The converter-amplifier accepts a 70-mc FM signal, converts it to frequencies in the 692 to 880-mc band and amplifies it to provide sufficient driving power for the 10-kw klystron power amplifier. Specifications are as shown in Table II.

A block diagram of the converter-amplifier is shown in Fig. 2. Local oscillator frequencies are selected in the range from 51.8 to 59.4 mc to minimize spurious responses in the 70-mc band in the IF arm of the mixer. Frequencies from the local oscillator are multiplied and amplified by the multiplier chain and applied to the mixer at a fixed level of approximately 4 watts. The 70-mc input frequencies are amplified and applied to the mixer at an adjustable level of approximately 1/2 watt. The beat frequency obtained in the mixer is then selected by means of tuned circuits and amplified to the required power level.

The stability of the output frequency of this system is a function of the stability of the local oscillator and of the incoming 70-mc signal. To reduce the total carrier frequency drift to a value acceptable to the system, the local oscillator has been designed for a total frequency change of one part per million per day. The multiplied local oscillator frequency is above that of the carrier for output frequencies of 840 and 880 mc and below that of the carrier for 692 and 740 mc.

The converter-amplifier consists of four 19-inch, rack-mounted chassis in a 7-foot cabinet with front and rear access doors, as shown in Fig. 3. The top half contains the RF (radio frequency) chassis, with the power supply and voltage regulator in the lower half. The operating facilities on the front which are accessible without interrupting the interlocks are: the metering panel, tuning of local oscillator and multipliers, and tuning of mixer amplifier. The last two are available through doors in the protective dust cover. Power control and circuit breakers, and a line voltage meter are available on the front panel. A ventilating fan, with replaceable filter, is mounted on the inside of the rear door. The rear door is interlocked with the high-voltage controlling relays and when opened the high voltage is turned off.

RF CHASSIS

The RF chassis, Fig. 4, in addition to providing a mounting surface for the detachable IF power amplifier and RF multiplier subchassis, also contains the mixer-amplifier chain, metering facilities, monitoring circuits, fan and manifold, interlocks, and alarm circuitry.

Paper 58-179, recommended by the AIEE Radio Communications Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted June 26, 1957; made available for printing December 2, 1957.

R. A. FELSENHELD, H. HAVSTAD, J. L. JATLOW, D. J. LEVINE, and L. POLLACK are with the Federal Telecommunication Laboratories, Nutley, N. J.

The successful development of this equipment is due to the teamwork and co-operation of a large number of people. The authors are grateful to the following engineers for their contributions: A. G. Kandoian, for the initial planning and over-all supervision; W. Sichak, for over-all technical supervision; J. Gulack for the system layout; W. Glomb, H. E. Lott, and J. Simkovich, for the converter-amplifier; L. Gray, H. Goldman, and W. Jacobus, for the power amplifier; R. T. Adams, A. T. Brown, and R. Bresk, for the receiver; and L. Juhas, for the feed horn. The requirements and equipment specifications for the system were set up by a joint committee of representatives of the Bell Telephone Laboratories, the Long Lines Department of the American Telephone and Telegraph Company, the Western Electric Company, the International Telephone and Telegraph Corporation, and the Federal Telecommunication Laboratories. Special acknowledgment is due to the following members of the Committee: K. P. Stiles and A. A. Bottani of the Long Lines Department, American Telephone and Telegraph Company; and H. E. Curtis, N. F. Schlaack, and H. A. Wells of the Bell Telephone Laboratories.

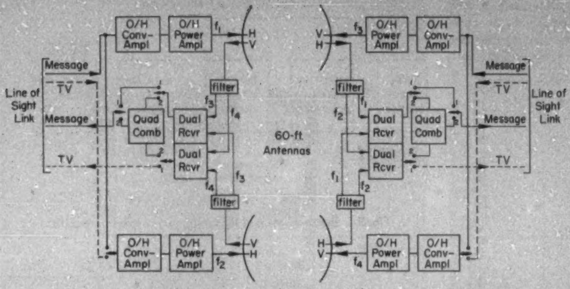

Fig. 1. Block diagram of complete wide-band O/H system showing major components

Table I. System Specifications

Features	Requirements
Transmitter power	10 kw.
Antennas	60-foot parabolic reflectors (two at each end) with dual polarization feed horns.
Diversity	Quadruple (space and frequency); may be used as two dual diversity systems; IF (70 mc) combining used.
Service	System input and output 70-mc FM signal; capable of handling at least 120 telephone channels; may also be used simultaneously for TV transmission.
Frequency band	680–900 mc.
Transmission lines	*WR-1150* wave guide for transmitting line, pressurized; $3^1/_8$-inch Styroflex cable for receiving line, pressurized.
Bandwidth	15 mc, 1 db down; 19 mc, 3 db down: with suitable terminal equipment, 6 mc, 1 db down video to video.
Envelope delay distortion	Suitable for multihop, multichannel telephone or wide-band television transmission; see text.
Noise loading distortion products	More than 50 db below signal level.
Safety features	All equipment fully interlocked and protected; key interlocks used in power amplifier.
Alarm and metering circuits	All equipment fully equipped with alarm circuits and contacts for external alarms; metering and test points incorporated for alignment and maintenance.
Environmental	Continuous operation in tropical climates.

Three types of metering and monitoring circuits are available.

1. Two panel meters to monitor certain points which indicate satisfactory operation of the equipment.
2. Test points, on a jack panel accessible without turning the equipment off, with the proper test equipment to determine transmission characteristics of the equipment.
3. Each vacuum tube is connected to a test jack for measuring the cathode current by means of one of the panel meters.

The ventilation system is located on the rear of the chassis and consists of a 115-cubic-foot-per-minute blower with a distribution manifold and individual air ducts leading to each tube to be cooled. Failure of the blower is indicated by a relay and alarm buzzer activated by an air-flow switch, as well as by a lamp located on top of the cabinet.

Two devices are used for protection against exposure to high voltage. The first device employs interlock switches in the front dust covers and rear cabinet access door. The second employs gravity-operated short-circuiting bars, operated by removal of the front dust covers and the rear access door.

STABLE OSCILLATOR

The oscillator consists of a stable, crystal-controlled oscillator and a buffer amplifier. The tubes used are one *12AT7* and one *404A*. The crystal is temperature-controlled and operates in its fifth overtone from 51.8 to 59.4 mc with a stability of 1.0 parts per million per day. The output is about 2 volts into a 90-ohm load.

RF MULTIPLIER

A chain of four tubes multiplies the frequency received from the local oscillator and amplifies the power to a level sufficient to drive the high-level mixer. The multiplication factors are 12 for output frequencies of 622 to 670 mc and 16 for output frequencies of 910 to 950 mc. The tubes used are one *2C51/396A*, one *418A*, and two *2C39B*'s. The relative power levels and frequency distributions along the multiplier chain are shown in Fig. 5. One volt across the 90-ohm input impedance is required for a 3-watt output.

The coupling circuits used between the first three tubes are conventional, lumped-constant, tuned circuits with a radial transmission-line cavity terminating the fourth tube. An adjustable coupling loop in this cavity couples the power to the input of the mixer.

The envelope temperature is kept below approximately 100 degrees centigrade by means of air cooling on all tubes except the *2C51*, and the total power dissipation in any tube is below 50% of the rated dissipation for the tube.

IF POWER AMPLIFIER

The IF amplifier is a broad-band 6-tube 5-stage unit which amplifies the 70-mc signal. It will deliver an output power adjustable between 0.1 to 1.5 watts

with an input signal of 7 milliwatts across 75 ohms. The tubes used are one *417A* grounded-grid input stage, two *404A*'s and one *418A* interstage, and two *418A*'s in a push-pull output stage; see Fig. 6.

The input coupling network is provided with a matching adjustment consisting of bias control of the input tube and a single-tuned broad-band cathode inductance. A matching adjustment is necessary because the input to this amplifier may be fed by a relatively long transmission line, and also to minimize distortion due to reflections.

Most interstage coupling networks are adjustable equivalent T transformers with a passband amplitude response of 0.1 db over a 20-mc band centered at 70 mc. Exceptions are the coupling between the fourth and fifth stages, and the output transformer where fixed coupled transformers are used.

Three methods are used to minimize variations in amplifier gain resulting from tube aging and supply voltage fluctuations. These consist of: 1. regulation of the filament power supplies by use of a

MIXER-AMPLIFIER

The mixer-amplifier consists of three *2C39B*'s in double-tuned radial transmission line cavity-coupling networks. The required bandwidth is obtained by using stagger-damped interstage coupling and single-tuned broad-band output coupling, giving an over-all 3-peaked response having a peak-to-valley ratio of approximately 1/4 db over a 20-mc bandwidth.

The mixer-amplifier, Fig. 4, consists of a mixer, two ultrahigh-frequency amplifiers, and radial transmission line cavities. Each tube has one cathode cavity and one plate cavity. Broad bandwidth is obtained by adjusting the coupling between the plate cavity of one stage and the cathode cavity of the following stage. The local oscillator power is coupled to the cathode of the mixer tube by means of a radial cavity, and the IF power is introduced through a broad-band lumped-constant network. The plate cavity of the mixer is loop-coupled to the cathode cavity of the first amplifier, and proper coupling is obtained by the relative values of two tuning capacitors in the amplifier cathode cavity.

A similar coupling arrangement is used between the first and second amplifiers. The second amplifier plate circuit is a single tuned cavity, loaded to the required Q by the 50-ohm load on the output loop. Capacitive-tuning plungers, inserted parallel to the axis, tune each cavity.

POWER SUPPLY

The power supply is unregulated and supplies all direct and alternating voltages. Voltage regulation of ±1% is obtained from an automatic, line-voltage regulator mounted below the power supply.

A 60-second time delay between the application of filament power and plate power provides time for filament warm-up.

All high voltages are connected through relays on the primary side of the transformers which are operated by the interlocks on the rear cabinet door and front dust covers.

Power Amplifier

The converter-amplifier output at approximately 10 watts is amplified to 10-kilowatt level by the power amplifier. The required 30 db of gain is obtained with a 6-cavity klystron (type *X631*, by Eitel-McCullough, Inc.). This klystron and a set of tuned circuits covers the band from 680 to 900 mc.

Amplifier

Since the velocity modulation action at the gaps and the density modulation in the drift spaces are frequency-sensitive mechanisms, the klystron is inherently a narrow-band device. However, by utilizing broad-band tuned circuits at the klystron gaps, bandwidths of 3% to 4% of center frequency can be achieved.

The amplifier assembly is shown in Fig. 7. The klystron assembly is on the left and the controls for the focusing-coil power supplies are on the upper right panel. The lower right-hand section houses the klystron filament transformer and the semiconductor rectifier for the focus supplies. Circuit breakers and overload indicators are aligned along the center panel, and meters indicating the klystron parameters are in the top panel.

The klystron assembly, Fig. 8, shows in greater detail the double-tuned circuits surrounding each klystron gap. The circuits across the first five klystron gaps consist of coaxial lines coupled to rectangular wave-guide cavities. A wave-guide section surrounds the klystron gap. To handle the high power level, the output circuit is formed by two wave-guide cavities coupled together with an iris located in the common wall between the guide sections. A lumped-circuit equivalent of these tuned circuits is shown in Fig. 9.

The desired bandwidth is achieved by loading each circuit with an external resistor. In the input circuit, the wave-guide section is loaded and the input signal is coupled to the coaxial section of the double-tuned assembly. Coupling and loading are adjusted to obtain maximum power transfer and maximal flatness of response (equal primary and secondary Q).[1] The interstage assemblies are loaded on one side only (the secondary coaxial section) to achieve the maximum impedance across the klystron gap for the given bandwidth.

The output primary tuned circuit is loaded by the klystron beam impedance; the secondary is loaded by the antenna impedance coupled through a capacitive probe. The loading resistors used in the first three tuned circuits are air cooled. The fourth and fifth circuit resistors are $1\frac{5}{8}$-inch coaxial-line water-filled loads.

To simplify the alignment of the amplifier, the six tuned circuits are synchronously aligned and centered about the carrier frequency. Each circuit is initially adjusted for transitional coupling with the klystron unenergized. A sweep signal generator is coupled to one circuit at a time and the response observed at the test point incorporated in the circuit. Then, under normal drive and power input conditions, a slight readjustment of the circuit parameters will result in the desired response. It should be noted that increased efficiency and gain may be obtained by "stagger damping" but at the expense of considerably greater adjustment difficulties.[2]

Power Supplies

The primary power to all filaments, to the klystron bombarder supply, and to the electromagnetic focusing supplies is regulated by an automatic motor-driven induction regulator to assure maximum tube life and minimum variation in klystron-operating conditions.

All high-voltage magnetic components are nonflammable-oil-filled. The bombarder supply and beam supply are unitized assemblies, i.e., the magnetic components are contained in one oil-filled tank.

The bombarder supply utilizes Xenon-filled rectifiers, whereas the beam supply utilizes high-vacuum diodes to minimize the possibility of rectifier arcback. The circuits of both supplies are the 3-phase bridge type. The beam supply delivers 20 kv at 2.5 amperes. Filtering of this unit is adequate to limit the incidental

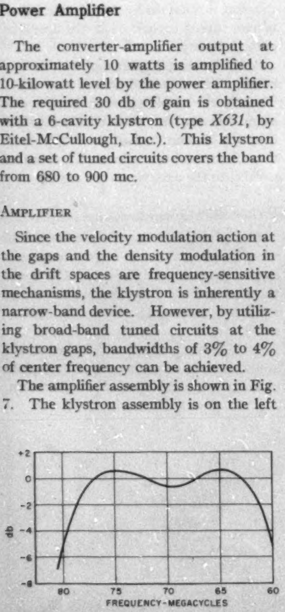

Fig. 14. **Over-all amplitude response versus frequency through converter-amplifier, power amplifier, and receiver**

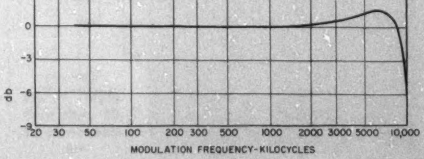

Fig. 15. **Over-all amplitude video-to-video amplitude response, including wide-band modulator and demodulator**

Fig. 16. Sixty-foot parabolic antennas at Guanabo, Cuba

FM to less than 100 cycles per second rms. Continuous variation of the beam voltage is possible at the amplifier control panel, over the range from 10.5 to 20 kv at the nominal line voltage ±10%.

Controls

Control and overload monitoring circuits are arranged to provide proper sequential application of the various voltages and to protect the equipment against progressive damage resulting from component failures or overloads.

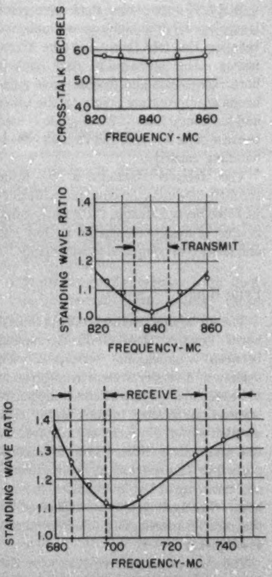

Fig. 17. Standing wave ratio and crosstalk of a typical dual-polarization feed horn

All a-c circuits are monitored and switched by magnetic-trip circuit breakers with an appropriate tripping time versus current characteristic which will accommodate starting current surges but also allow rapid tripping under large overload conditions.

High-speed d-c relays monitor the following parameters: beam current, drift tube current, fifth and sixth cavity voltage, excessive output transmission line mismatch, and low RF output. All of these relays except the low RF output will trip the beam power supply circuit breaker in less than 50 milliseconds. Pilot-light indications and an alarm calls attention to a fault. In addition to electrical interlocks, the necessary mechanical interlocks such as liquid coolant flow, air flow, and high-voltage grounding switches are incorporated.

Cooling

Since the collector and drift tubes require liquid cooling, a closed system (coolant to air or coolant to water unit) is provided for each amplifier. Where an adequate supply of well water is available, the latter type of cooler is preferred. The air-cooled unit is shown in Fig. 10 and the water-cooled unit in Fig. 11. The coolant, a mixture of ethylene glycol-distilled water (60 to 40 parts per volume) with an acidic inhibitor, is also used as the dissipative element in the klystron fourth and fifth cavity loads.

Performance

Over-all transmission response of the converter-amplifier, plus power amplifier is shown in Fig. 12; the oscillogram shown was taken at 840 mc. Note that the 3-db bandwidth is 19 mc, and the 1.0-db points approximately 15 mc. Saturation power is 10.5 kw at the upper end of the band (880 mc) and it falls to 8 kw at the low end of the band (690 mc).

Gain at the level 0.5 db below saturation power is 32 db at the high-frequency end of the band and 28 db at the low end for the bandwidths shown. For smaller bandwidths, the gain can be increased to as much as 48 to 50 db before instability problems arise.

Envelope delay versus input frequency of the system, including the wide-band terminal equipment, converter-amplifier, power amplifier, and receiver is shown in Fig. 13. The envelope delay curve is resolved into three components to obtain a standard basis of comparison; the slope component is found by drawing a straight line between the frequency points of interest, such as 66 mc and 74 mc of Fig. 13; the difference in time delay noted between the two points is the slope. The change in envelope delay remaining after subtracting the slope component is the parabolic component, provided ripple is negligible.

Fig. 18. Outline drawing of dual-polarization feed horn

If appreciable ripple is present, this must be averaged about the slope component and subtracted from the total envelope delay; the remainder is the parabolic component. Thus, the sum of the three components at each frequency should equal the recorded curve. The components of time delay are as follows:

	Time Delay, Millimicroseconds	
Component	**At ±4 Mc**	**At ±6 Mc**
Parabola	15	22
Slope	25	30
Ripple	±2	±2

Over-all response from IF input to the converter-amplifier to IF output at the receiver is shown in Fig. 14, and the video-to-video response from the transmitting terminal through the radio system and the receiving terminal is shown in Fig. 15. Intermodulation distortion is 50 db down, as measured through the system with a 500-kc bandwidth noise source producing an rms deviation of 0.4 mc.

Antenna System

The antenna system consists of two 60-foot paraboloidal reflectors at each site, fed by dual polarized horns, each of which is connected to one transmitter and two receivers. The transmission line connecting the transmitters to the antennas is *WR-1150* wave guide, and the receiver connection is via $3^1/_8$-inch 50-ohm Styroflex cables.

REFLECTORS

The reflectors and feed-horn support structures are shown in Fig. 16.

TRANSMISSION LINES

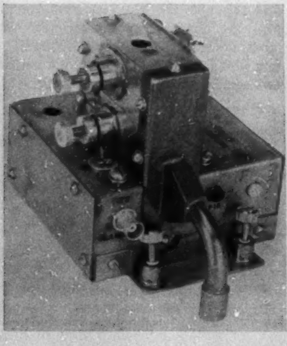
WR-1150 copper-clad steel wave guide is employed for the high-power connection between the feed horn and the transmitter. The wave-guide runs include both rigid bends and flexible wave-guide bends at appropriate points on the tower and horizontal lines. Wave guide is used because of its low loss, and its high power-handling capacity.

The receiver connection is made through $3^1/_8$-inch, 50-ohm polyethylene-jacketed Styroflex cable. This large cable is used primarily because of its low loss and lower cost compared to wave guide.

FEED HORN

The use of dual, orthogonally polarized horns (greater than 50-db decoupling between polarizations) permits a wide variety of diversity system arrangements to be employed. In particular, the polarizations are selected in such a way that no high-power diplexers are required in the transmitter lines. This is accomplished by transmitting at one frequency and receiving at two frequencies, in each horn. Received signals are separated by the receiver-preselecting filters arranged as a diplexer.

The dual polarized feed horns for the 60-foot paraboloidal reflectors were designed to direct a signal at the reflector edge at a level of approximately −10 to



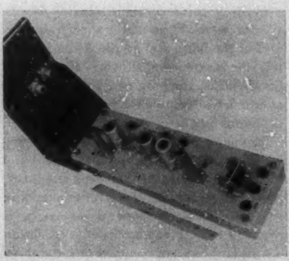


Fig. 23. Microstrip mixer and 70-mc preamplifier

Fig. 22 (left). Low noise RF amplifier

−12 db relative to the signal directed toward the reflector vertex.[3] Typical data are given in Fig. 17. Since the horns were designed for a specific application, no particular effort was directed toward broad-band development.

An outline drawing of the horn is shown in Fig. 18. Short capacitive posts were employed to watch the horn at the individual transmitter frequency bands. This was necessary to obtain the required low VSWR (voltage standing wave ratio), less than 1.08, over the transmitter band. The receiver connections were matched by proper selection of probe length and diameter and by the fin position relative to the probes.

The horns have been satisfactorily tested with 10-kw continuous-wave power fed into the wave-guide connection. The transmission lines and horns will operate with approximately 1/2-psi (pound-per-square-inch) (gage) internal dry air pressure, and have been tested with over 2-psi (gage) internal pressure.

The horn aperture barrier is a gasketed 1/8-inch-thick teflon-fiberglass sheet clamped to the aperture flange. Fig. 19 shows a completed horn, ready for installation. The horn weighs approximately 150 pounds. The maximum dimensions are approximately 14 by 14 by 46 inches.

The antenna system performance may be described as follows: The free-space gain at mid-band is 41 db, not including feed line loss, and the half-power beamwidth is 1.4 degrees, mid-band.

Diversity Receiver

The quadruple diversity receiver set comprises two dual-diversity reciever sets operating at different frequencies in the range 680 to 900 mc with means for combining at the 70-mc IF frequency into one 70-mc output.

Fig. 20 shows the receiver with dust covers removed. Two 9-foot racks (joined together at the center) hold the various 19-inch subchassis panels. Available components such as IF amplifiers, equalizers, and receiver control units, are used wherever possible.[4] Preselectors, mixers, local oscillator-multipliers, combiners, diversity switching panel, power distribution and alarm panels are designed specifically for this system.

Fig. 21 is a simplified block diagram. Preselectors are provided to separate the two frequencies from each antenna line for each of the four receiving channels. Each signal passes through an RF amplifier and mixes with the output of a crystal-controlled local oscillator multiplier to produce a 70-mc IF. The pre-IF amplifiers, equalizers, attenuators, and main IF amplifiers deliver the proper level for phase combining. There are three phase combiners, one for each dual-diversity channel, and one to combine the dual-diversity outputs for quadruple combining. To meet the over-all delay distortion and amplitude response requirements, each major component of the receiver was so designed that the 0.1-db bandwidth is about 20 mc.

Diplexer Filter

The diplexer is composed of two 3-cavity maximally flat amplitude response filters, centered at 692 and 740 mc respectively, (or 840 and 880 mc) coupled to a T-junction. The branch legs to each filter are a quarter wavelength at the center frequency of the other filter so that short circuits at the filter inputs are reflected as open circuits at the diplexer junctions. The correct leg is a matched line (SWR under 1.1). The filter specifications are:

Response, Db Bandwidth	Megacycles	Insertion Loss	Decibels
0.1	18.5	center frequency	1/2
1.0	30	other received frequency	30
3.0	38	transmitter frequencies	50
40	175		

RF Amplifier

A single *416B* tube is used in a grounded grid RF amplifier stage. Fig. 22 is a top view. The input SWR is less than 1.3 over a 20-mc bandwidth. The plate circuit has two resonant transmission lines provided with adjustable coupling and an output impedance of 50 ohms. Gains of 14 db and noise figures under 8 db are obtained.

Mixer Preamplifier

Microstrip construction is used in the balanced mixer.[5] The crystals (types *1N21B* and *1N21BR*) are each matched to a 50-ohm line by a short-circuited stub of proper length and position. Decoupling between the signal input and the local oscillator arm is greater than 20 db. The signal input SWR is under 1.3 for a 20-mc bandwidth. The mixer is attached directly to the pre-IF amplifier, Fig. 23, and feeds the cathode of the first of three cascaded stages.

Main IF Amplifier

A wide-band IF amplifier, eight tubes in cascade, is used to provide 60-db gain at 70-mc center frequency.[4] The 3-db bandwidth is 32 mc, and the 0.1-db bandwidth is 20 mc.

Local Oscillator: Multiplier

The crystal-controlled local oscillator, Fig. 24, uses a *12AT7* twin triode in a cathode coupled circuit at frequencies in the 50-mc range. The output triode section is tuned to twice the crystal frequency. Two *404*-type tubes follow in cascade, the first as a 100-mc amplifier and the second as 300-mc tripler. This drives the grounded grid output (*2C39*) tube either as a doubler or tripler in the frequency range 620 to 950 mc.

Phase Combiner, 70-Mc

Diversity reception is made possible by locking two 70-mc IF signals and adding them in phase. The phase detector supplies a d-c control voltage to the local oscillator, which in turn adjusts their frequencies to produce phase lock. Except for two semiconductor diodes, the combiner uses only passive circuit elements. Part of the combined output voltage is used for automatic gain control and controls the main IF amplifiers. The 70-mc outputs of the dual combiner connect to the diversity switch panel.

Diversity Switching Panel

Outputs from the dual combiners are switched by coaxial relays to separate jacks or to a third combiner for quadruple operation. Automatic gain control voltages are simultaneously switched for either type of service. Fig. 21 shows the system diagram for a quadruple receiver.

Power Distribution and Alarm Panels

Each dual-diversity receiver is separately powered by external lines from a commercial power supply. Incoming power is controlled by master switches, and circuit breakers and fuses. The alarm circuitry monitors the blower operation, the RF level, and the IF output; and 3-phase lock conditions actuate an audible alarm whenever their operation is abnormal.

A MIAMI-HAVANA radio system, consisting of the wide-band over-the-horizon system discussed in another paper,[1] together with *TD-2* microwave links at each end, has recently been placed in service. This paper discusses the over-all radio system, its method of operation, and some of the test results obtained during its initial line-up.

Over-All System Description

The Miami-Havana radio system, developed to provide both telephone and television facilities, is divided into three sections. Starting south from Miami, Fla., two links of *TD-2* microwave equipment (totaling 37 miles) are used to connect the Miami terminal equipment to the over-the-horizon equipment at the Florida City radio station. From Florida City to Guanabo, Cuba, the 185-mile jump is made by means of the over-the-horizon equipment previously described; see Fig. 1. Between Guanabo and Havana a 14-mile *TD-2* microwave link is used to connect the over-the-horizon equipment to the terminal equipment. The standard *TD-2* FM (frequency modulation) signal is passed to and from the over-the-horizon equipment at a 70-mc (megacycle) intermediate frequency. The FM terminals for both telephone and television services are located at Miami and Havana.

Two separate radio systems are provided in each direction. At each end the *TD-2* links are operated in the common carrier band of 3,700 to 4,200 mc. At Florida City the over-the-horizon transmitters operate on 840 and 880 mc, and at Guanabo frequencies of 692 and 740 mc are used. Since these frequencies are in the ultrahigh-frequency television range they were co-ordinated with existing and proposed television station assignments in southern Florida to minimize chances of interference. Each over-the-horizon transmitter frequency is received on a space diversity basis, and arrangements are available to permit reception on a quadruple-diversity basis when required. A block schematic is shown in Fig. 2.

Since the radio station at Florida City is constructed in the Everglades, southeast of Florida City, an area subject to flooding under unusually high tide conditions, it was necessary to fill in the area used for construction of the building and the antenna assemblies. All construction is of a type designed to withstand winds of hurricane force. Fig. 3 is a view toward the horizon from the Florida City station. At Guanabo the station is located on the crest of a hill some 200 feet above the terrain immediately in front of it and has an unobstructed path to the horizon. Fig. 4 is a view toward the horizon from the Guanabo station.

The Florida City–Guanabo radio system provides two radio space diversity channels ordinarily used on a regular and protection basis. With automatic switching in the *TD-2* links, and the over-the-horizon channels fed in parallel from the *TD-2* channels selected by the automatic switching equipment, the over-all system is designed to provide as nearly continuous service as feasible. At Miami and Havana *L*-type carrier terminals provide connections to the land line systems of the two countries. In Miami this carrier terminal equipment is located in the telephone building where all other message circuits are terminated. In Havana the terminal equipment is located in the Radio Corporation of Cuba offices and connected by cable to the switchboards located in the Cuban Telephone Company office about a mile distant.

For television service, television operation centers are located at the Telephone Company office in Miami and the Havana office of the Radio Corporation of Cuba, and connections to television networks or stations are made from these points. When television service is required, use is made of the protection facilities and the telephone system is operated without benefit of the protection switching arrangements. Fig. 5 is a view of the front of the Florida City station.

Transmission Characteristics

During the initial tests, recordings were made of the incoming RF (radio frequency) signal level both to compare transmission on the two individual radio systems and to verify the path loss of 197 db (decibels), between isotropic antennas, previously determined. The two radio systems showed the same average fading characteristics although the instantaneous input levels were usually different. The 197-db path loss was verified, but recordings will be continued for some time to determine what daily and seasonal characteristics the path may have.

The basic transmission characteristics of the beyond-the-horizon path vary continuously because of selective fading resulting from multipath transmission. This amplitude and phase distortion is reflected in instability in the recovered base-band signal. Since the side bands furthest removed from the carrier of the FM wave are most affected in amplitude and phase relative to the carrier by selective fading, it is only to be expected that this instability would increase with base-band frequency. Relatively stable transmission was observed up to about 1 mc, with increasing instability to the top of the video band.

However, the higher frequency components of a working monochrome television signal are quite small, so that occasional loss or distortion of these components will cause picture distortions which are usually apparent only to a trained observer. This characteristic makes it possible to provide a good television picture on the over-the-horizon system. However, momentary loss of horizontal or vertical synchronization is immediately evident, and it is necessary that these signal components be relatively undistorted. The relatively stable characteristic of the low frequencies in the over-the-horizon system meet this requirement. In contrast to television, multiplex telephone transmission distributes the energy of individual components across the band much more uniformly. It would not therefore be possible on this system to occupy fully the same frequency band employed for television with a similar band of telephone channels. Telephone channels are thus limited to a base band of about 1 mc.

Paper 58-154, recommended by the AIEE Radio Communications Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted October 18, 1957; made available for printing November 12, 1957.

K. P. STILES, F. G. HOLLINS, and E. T. FRUHNER are with the American Telephone and Telegraph Company, Long Lines Department, New York, N. Y.; and W. D. SIDDALL is with the Radio Corporation of Cuba, Havana, Cuba.

The construction of the over-all Miami-Havana radio system was the result of co-operation by several companies, which include the Radio Corporation of Cuba, the Federal Telecommunication Laboratories, the Long Lines Department of the American Telephone and Telegraph Company, the International Telephone and Telegraph Company, and the Bell Telephone Laboratories.

Fig. 1 (left). Layout map of Florida-Cuba over-the-horizon radio system

This over-the-horizon system presently employs FM with a deviation of ±1 mc. The base band initially employed for the telephone circuits is 300 to 550 kc. The base band for television service is the nominal bandwidth of the television signal. The telephone and television signals are pre-emphasized with the use of the corresponding pre-emphasis networks presently in use on type *TD-2* facilities. Tropospheric selective-fading characteristics require additional limiting for FM demodulation to that required by line-of-sight systems such as the type *TD-2* system. This over-the-horizon system is therefore provided with 50 db of limiting which provides reasonable stability of base-band output level.

As the telephone or television signal components are confined within a band of approximately 9 mc around the carrier, the received band is correspondingly limited to this by a filter to minimize noise and improve the system fade margin. Similarly, adjustment of the transmitter bandwidth to 11 mc permits improved operation of the over-the-horizon transmitters. At the Florida terminal, where transmitting frequencies of 840 and 880 mc are used, output powers of 8 to 10 kw were obtained with a d-c input of about 45 kw when tuned to provide maximum bandwidth. When the amplifier cavities were tapered to give an output band-

width of about 11 mc, the efficiency increased sufficiently to permit the same output power with a beam voltage of 19 kv as compared with 20 kv for the wider band output. At the Cuban terminal, some increase in output power was obtained by similar methods. These increases in output power further improved the fading margin.

The median RF signal-to-noise ratio is about 47 db with the adjustments indicated in the foregoing. Variations occur in the received signal level, and path loss tests on this path indicate that long-term fades in excess of 20 db below the median value may occur about 2% of the time. Even for average signals of 20 db below the median value, the signal-to-noise ratio should be quite adequate. For example, with the median RF signal-to-noise ratio of 47 db, the base-band video signal-to-noise ratio will be 48 db on the basis of peak-to-peak signal to rms noise.

The FM deviation of any system is, of course, a compromise between fluctuation noise at low deviations and distortions or instability at high deviations. Although a deviation of ±1 mc is presently employed as an optimum, future equipment developments may allow greater deviations. The over-the-horizon transmitting and receiving equipments will not be a limiting factor since these equipments are designed to provide for bandwidths considerably wider than those now in use.

Accordingly, the use of pre-emphasized FM with a nominal deviation of ±1 mc and with limiting of 50 db, as well as the conventional restriction of the equipment bandwidth to that required for the signal products, provides satisfactory transmission of high-capacity multiplexed telephone signals or monochrome television signals.

Telephone Service

The telephone circuits are presently subject to level variations of less than ±1.0 db over protracted periods. As indicated previously, these circuits occupy base-band frequencies under 550 kv. However, it is expected that level variations in the base band should be tolerable up to 1.0 mc most of the time.

Envelope delay distortions and other crosstalk-producing factors are such that strong single-frequency tones will produce relatively strong modulation products. For example, it was necessary to reduce the level of a 64-kc pilot tone by 10 db below the normal level employed on type *TD-2* systems to a level 24 db below the nominal telephone channel in order to minimize cross-modulation between circuits separated by 64 kc. With this modification, the system handled a test load of 180 telephone circuits quite satisfactorily.

Tests were made with a load of 180 telephone circuits, or three full supergroups, employing base-band frequencies up to 750 kc. With this load the individual circuits had a noise level of 22 decibels adjusted at the zero level point. This is about 10 db better than the design objective for telephone circuits of this length. These results indicate the practicability of operating four supergroups (240 circuits) if conditions prevailing during the initial period are representative of future conditions.

During the interval in July and August, 1957, available for testing the Miami-Havana radio systems, the incoming median RF signal levels varied from −10 to +20 db with respect to the expected median of about 50 db below 1 milliwatt. Under these conditions the telephone transmissions are excellent. Computations based on path loss tests and available data on fading rates and magnitudes indicate that a service availability may be expected of 99.99% from a propagation standpoint.

Television Service

Although tropospheric propagation has been employed elsewhere for a limited number of telephone circuits, this project represents the first attempt at television transmission. No information was available regarding envelope delay distortion, response variations, and other characteristics. In view of this, the over-the-horizon facilities were designed to have a sufficiently wide bandwidth to permit optimum operating conditions for television without restrictions or limitations from the facilities themselves.

The principal problem affecting television transmission is the stabilization of the synchronizing components. The transmission features of this system discussed in the foregoing were effective in providing the needed stabilization. For example, tests of non-pre-emphasized transmission with a deviation of ±4 mc on a wide-band basis disclosed severe instability of synchronization as well as severe distortion of picture content, together with substantial level variations.

It should be noted that satisfactory transmission of monochrome television signals has been achieved under the conditions so far observed without the use of sync-regenerating equipment. Regenerating equipment for both the vertical and horizontal synchronizing pulses should prove advantageous under severe propagation disturbances and the design of such equipment is receiving further study.

Limited tests of color television transmission showed unsatisfactory results, primarily because of level instability of the system at the 3.6-mc color carrier frequency. Successful transmission of color transmission in the future depends on the possibility of devising some method of stabilizing the color carrier and its side-band frequencies.

Conclusions

As presently installed, the Miami-Havana radio system provides for an ultimate message capacity of well over its designed capacity of 120 circuits. During normal operations, when only telephone messages are being handled, the use of duplicate facilities, each with space diversity in the over-the-horizon link, permits the use of automatic switching in the *TD-2* links, with restoration in less than 75 milliseconds. Under extremely adverse transmission conditions on the over-the-horizon section, quadruple diversity, a combination of both space and frequency diversity, may be used.

In conclusion, it appears that the use of over-the-horizon tropospheric scatter links of the type described will provide reliable radio systems for telephone or television service. Where terrain conditions are such that single hops of the order of 200 miles are required, systems of this type offer advantages over other transmission methods. It appears that where intermediate repeaters can be provided and maintained, line-of-sight transmission is better in propagation stability, has comparatively less multipath fading, provides greater availability of frequency assignments, and is lower in cost. The over-the horizon systems are expected to be particularly advantageous for connecting islands, for crossing isolated regions with rugged intermediate terrain, and in areas where frequency congestion in the radio frequency bands between about 500 and 2,000 mc is not severe.

A New Broad-Band Microwave Antenna System

R. W. FRIIS
NONMEMBER AIEE

A. S. MAY
NONMEMBER AIEE

RADIO RELAY in the Bell Telephone System now provides over 13 million miles of 2-way message circuits, approximately one fourth of all the long-distance telephone circuits in this country. It also provides about 62,000 miles of broad-band radio channels which make network TV (television) available to over 500 TV broadcasting stations in 350 cities. This rapid expansion of radio relay facilities indicated some time ago that by 1955 portions of the central transcontinental and other backbone routes would be loaded to their capacity of six broad-band channels in each direction of transmission. Continued expansion would require the development of new radio relay systems in the higher frequency bands assigned by the Federal Communications Commission for common-carrier use.

A new antenna called the "horn-reflector" antenna[1,2] and its associated circular waveguide were the first items developed for these new higher frequency radio relay systems. The horn-reflector antenna and its circular waveguide are designed for simultaneous operation in the common-carrier bands of 3,700 to 4,200 mc (megacycles) (*TD-2*), 5,925 to 6,425 mc (*TH*), and 10,700 to 11,700 mc (*TJ*). The letters indicate the abbreviated Bell System code for the respective radio relay system, the latter two of which are under development. The 6,000-mc *TH* system will be a long-haul system with eight broad-band channels in each direction of transmission, each channel capable of carrying about 2,000 message circuits, or a monochrome or National Television Systems Committee color television program. The 11,000-mc *TJ* system will be a short-haul system, each broad-band channel capable of carrying up to 240 message circuits or a monochrome or NTSC color television program.

Fig. 1 shows an installation of the horn-reflector antenna at Terrell, Tex., on the 4,000-mc *TD-2* radio relay system from Atlanta, Ga., to Dallas, Tex. The installation of this broad-band antenna and waveguide promises considerable savings when 6,000-mc long-haul and 11,000-mc short-haul systems are added to this and other backbone routes in the future.

Application

Fig. 2 illustrates that the horn-reflector antenna is basically an electromagnetic horn capped by a sector of a paraboloidal-shaped reflector. The apex of the horn coincides with the focal point of the paraboloidal reflector. The latter converts the spherical wavefront emanating from the feed horn to a plane or uniphase wavefront at the antenna aperture, thus ensuring maximum gain and minimum side lobe radiation.

The feed horn at the focal point of the antenna is designed with the proper hyperbolic contour to match a 2.812-inch-ID (inside diameter) circular waveguide with the frequency range 3,700 to 11,700 mc. A circular copper waveguide with a 2.812-inch ID has three important advantages over rectangular waveguides: 1. the loss for the dominant TE_{11}^{0} mode transmission at 4,000 mc is about 0.42 db (decibels) per 100 feet, approximately one half the loss of a 2.290×1.145 rectangular copper waveguide; 2. two signals polarized at 90 degrees to each other may be transmitted through circular waveguide, and by careful control of manufacturing processes a cross-polarization discrimination greater than 40 db per $12^{1}/_{2}$-foot section can be achieved; and 3. it is possible to transmit simultaneously dual-polarized signals in the 4,000-, 6,000-, and 11,000-mc common-carrier bands.

Propagation measurements over a typical radio link employing circular waveguide and horn-reflector antennas indicate that the net cross-polarization discrimination between vertically and horizontally polarized signals is greater than 20 db. By alternately polarizing adjacent channels of the 6,000-mc *TH* system this 20 db of discrimination or selectivity may be used to reduce the spacing between broad-band channels. As a result, a more efficient use is made of the frequency spectrum and a greater number of message circuits or television channels can be allocated in the 5,925- to 6,425-mc common-carrier band.

Because of their broad-band characteristics, only four horn-reflector antennas will be required at each repeater station on main backbone routes to handle all three systems at 4,000, 6,000, and 11,000 mc. As shown in Fig. 1, a transmitting and receiving antenna will be used on main backbone routes for each of the two directions of transmission. On spur or light routes, where no more than three or four broad-band channels are utilized in any one common-carrier band, one antenna may be used for both transmitting and receiving in one direction, thereby reducing to two the number of antennas per repeater station.

Fig. 3 shows schematically a horn-reflector antenna and circular waveguide system in which a finline[3] polarization separation network *A* may be used to separate the vertically polarized signals from the horizontally polarized signals in the 4,000-, 6,000-, and 11,000-mc systems. The signals then pass through system separation networks[4] *B*, *C*, *D* which separate the signals for each of the three common-carrier bands. Constant resistance networks[5] similar to those developed for the *TD-2* system may then be used to separate the various channels in a particular common-carrier band.

The tuning section illustrated in Fig. 3 is used at the bottom of each waveguide run to improve the cross-polarization discrimination. It is a 12-inch section of waveguide purposely deformed to have a cross-polarization discrimination (XPD) of 25 db, a value approximating the net XPD of the antenna and a long waveguide run. As one of the final steps in the alignment of an antenna waveguide system, the tuning section is rotated to improve the XPD to a minimum value of 30 db.

Transmission Characteristics

GAIN

The gain of the antenna with respect to an isotropic radiator or point source is shown in Table I. Also the efficiency of the antenna or the ratio of the measured gain to a computed area gain for the 64.5-square-foot aperture is indicated in decibels down from area gain, and in per cent.

HORIZONTAL AND VERTICAL DIRECTIVITY

Fig. 4 shows a typical radiation pattern on a 360-degree polar diagram for the horizontal directivity (azimuth) at 3,740

Paper 58-185, recommended by the AIEE Radio Communications Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2-7, 1958. Manuscript submitted July 26, 1956; made available for printing November 20, 1957.

R. W. FRIIS and A. S. MAY are with the Bell Telephone Laboratories, Inc., North Andover, Mass.

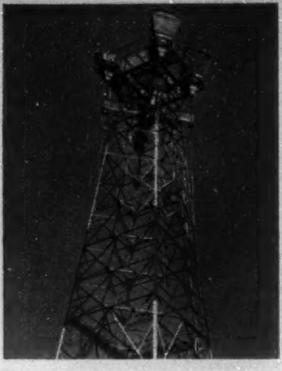

Fig. 1. Horn-reflector antenna installation at Terrell, Tex.

mc. The width of the beam between three decibel points, at 3,740, 6,325, and 10,960 mc is shown in Table II. At the higher frequencies the radiation patterns are similar to those shown in Fig. 4, except that even more of the energy is concentrated in the desired direction of propagation.

The vertical directivity (elevation) for both polarizations is also listed in Table II for the same frequencies.

The front-to-back ratio of the antenna, or its ability to discriminate against signals coming from the back (180-degree response), may be taken directly from the horizontal directivity patterns.

New antenna-measuring equipment has been developed which uses radar pulse techniques to achieve a higher order of accuracy in measurements of radiation patterns and crosstalk between antennas. In the past, measurements have been limited at times because of interfering reflections from nearby trees, buildings, and surrounding terrain. Magnetrons were developed for spot frequencies in the three common-carrier bands, and by their use the aforementioned extraneous reflections may be separated from the direct signal on a time basis, and thus a true plot of the radiation pattern and crosstalk obtained. However, the measured front-to-back ratios in Table II or the crosstalk characteristics in Table III may be reduced at a typical antenna installation because of ground return or reflections from the surrounding terrain.

CROSSTALK

The crosstalk or coupling between similar antennas in operating position at the same level on a tower is of particular importance when a 2-frequency allocation plan is used for the radio system. In this type of plan, different frequencies are assigned for transmitting and receiving, but the receiving antenna pointing to the west receives signals on the same frequency assignments as the receiving antenna pointing to the east. This is true also for the two transmitting antenna. Table III shows the measured back-to-back and side-to-side crosstalk of two antennas spaced on 20-foot centers. A pulsed test signal at a known level is sent into a transmitting antenna and the response or crosstalk is measured for different orientations of the receiving antenna.

CROSS-POLARIZATION DISCRIMINATION

The XPD of an antenna is a measure of the ability of the antenna to discriminate between two received signals at the same frequency, that are polarized 90 degrees with respect to each other. The maximum XPD of the horn-reflector antenna is shown in Table IV.

Fig. 5 shows the XPD of the main lobe of the horn-reflector antenna. Over the rest of the radiation pattern the responses to vertically and horizontally polarized signals are approximately equal. The utilization of cross-polarization to discriminate against interfering signals is therefore not feasible except within the directivity of the main lobe. Fig. 5 also illustrates how rapidly the XPD deteriorates if the antennas are misaligned or if their alignment is influenced by wind velocity, tower twist, or sway.

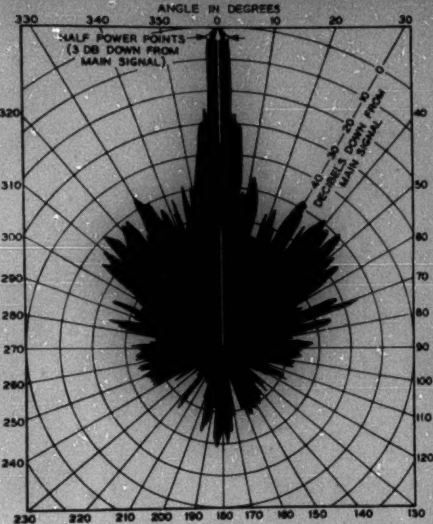

Fig. 4. Horizontal directivity of horn-reflector antenna at 3,740 mc

RETURN LOSS OR VSWR

One of the advantages of this type of antenna is its excellent return loss or low-voltage standing-wave ratio (VSWR) over the very wide frequency band from 3,700 to 11,700 mc. A good impedance match throughout the antenna-waveguide system is important in long-haul radio systems as the waveguide echoes or reflections from an antenna at the end of a long waveguide run may affect the message-handling capacity of the system.

The horn-reflector antenna tapers down with no internal projections to an aperture $11^1/_2$ inches square, to which is attached a precision-cast aluminum feed horn. The internal contour of the 21-inch-long feed horn continued the taper in a gradual hyperbolic transformation designed to match the antenna into a 2.812-inch-ID circular waveguide over the frequency range 3,700 to 11,700 mc. The glass-fiber weather cover across the antenna aperture is sloped to minimize reflections back to the focal point or feed horn. The weather cover is designed to take heavy wind loads without any auxiliary braces or supporting structure, thus minimizing reflections from such sources.

Table IV. Antenna Cross-Polarization Characteristics

Frequency, Mc	XPD, Db
3,740	46
6,325	51
10,960	53

The waveguide is drawn to precision tolerance, and each section is carefully fabricated and tested to ensure that its return loss is 50 db or more (VSWR maximum = 1.0065).

Table V shows the minimum return loss or maximum VSWR measured for a representative antenna of this type with a 2.812-inch-ID circular-waveguide feed across the 4,000-, 6,000-, and 11,000-mc common-carrier bands.

Fabrication

The horn-reflector antenna is shown in more detail in Fig. 6. The antenna is mounted on gimbal supports on a square I-beam mounting frame which in turn swivels on a circular mounting base. Provision is made for ±5-degree adjustments in azimuth and ±3-degree adjustments in elevation angle.

The antenna weighs about 1,700 pounds and is $20^1/_2$ feet high, 11 feet wide, and 9 feet deep. Its focal length is $7^1/_2$ feet, and the front and side angles of the horn are 30 degrees.

The sides of the horn are fabricated of 1/16-inch aluminum alloy reinforced by extruded aluminum "hat section" stiffeners.

The paraboloidal surface of the reflector is held to an accuracy of ±1/16 inch, which, at the highest operating frequency of 11,700 mc, is approximately ±1/16 of a wavelength. The reflector is fabricated in two parts with a dividing line from front to rear. A reflector skin for each half is formed by stretching a 1/8-inch aluminum alloy sheet over a glass-fiber reinforced plastic die having the desired paraboloidal contour. The reflector skins are attached to thick aluminum spars which have been routed to the desired contour. Formed horizontal ribs are attached in the reflector assembly fix-

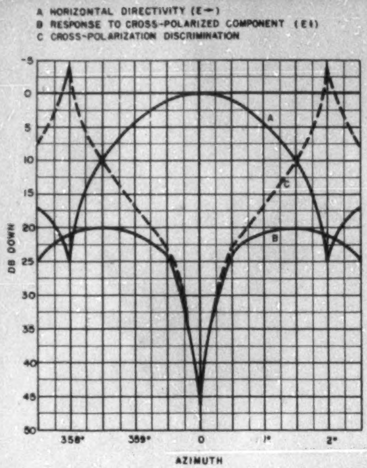

Fig. 5 (left). XPD of main lobe of horn - reflector antenna with azimuth ±2.5 degrees, and 3,740 mc

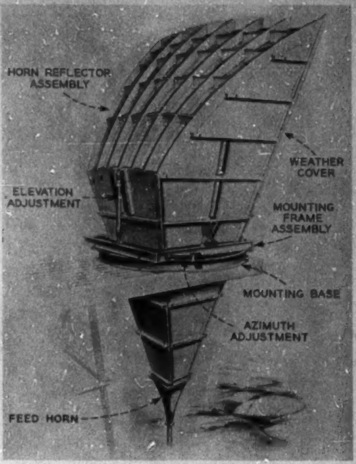

Fig. 6 (right). General view of horn-reflector antenna

ture. Rather extensive tooling was developed to ensure that the reflector surface was kept within tolerance and that the same parts of different antennas were interchangeable in production.

The antenna was designed to withstand heavy snow, ice, and wind loads of 100 pounds per square foot on flat surfaces, equivalent to average wind velocities of about 150 miles per hour. Static load tests up to 100 pounds per square foot were made on a preproduction model of the antenna, and the extensive instrumentation indicated that at this static load no part of the antenna was overstressed. The 64.5-square-foot aperture of the antenna is protected from the weather by a 4-ply polyester impregnated glass-fiber cover 0.040 inch thick.

All seams of the antenna are sealed against weather and radio-frequency leakage by a combination gasket employing nonvulcanized conducting rubber and a fine-woven wire mesh. Though primarily a weather seal, the conducting rubber also provides an important secondary protection against the leakage of microwave energy. The antenna is substantially airtight with a leakage rate of less than 15 cubic feet per hour. The antennas and waveguide at a typical installation are charged with dry air at a pressure of 30 pounds per square foot (0.2 pound per square inch) from a silica gel dehydrator to prevent condensation from affecting the transmission characteristics of the antenna-waveguide system.

The antenna is designed to be shipped from the factory completely assembled and pressure-tested, or packed in four boxes for field assembly at the repeater station site.

The waveguide is a low-phosphorus, high-conducitivity copper waveguide of 2.812±0.003 inches ID and a 3±0.006-inch outside diameter. The ovality or out-of-roundness is held to a difference of 0.004 inch between major and minor diameter at any point along the inside surface of the waveguide. A precision air gage has been developed which makes it possible to insert a measuring head in the waveguide under test and to read directly on an external meter the ID of the waveguide. The measuring device is accurate to ±0.0002 inch throughout its range of 2.812±0.005 inches. Since the XPD is dependent upon the out-of-roundness of the waveguide, the air gage is used by the drawing mill to check each length of tubing drawn. A corrosion-resisting steel flange is "cold-headed" on the copper waveguide, which has had a slight shoulder machined on each end. An O-ring gasket is used between sections of waveguide to ensure a pressure- and weather-tight joint.

The use of the horn-reflector antenna, circular waveguide, and a new design of system and channel-separating waveguide networks promises considerable economies in the expansion of Bell System long-haul radio relay facilities.

Data Transmission Testing Set

Synopsis: This paper describes a transmission testing set for high-speed data circuits. The set is an electronic, transistorized device intended primarily for laboratory use in the development of binary data transmission systems.

UNTIL RECENT YEARS the transmission of data in binary form was confined almost exclusively to telegraphic or similar low-speed communication systems. Transmission speed was limited by the rate of operation of printing telegraph or other terminal equipment. Distortion-measuring devices for determining the efficiency of synchronous or start-stop telegraph transmission circuits or equipment were well known to the art.[1,2] The recent introduction of integrated data-processing systems and computer centers requires the transmission of voluminous information in binary form and at high speeds. To develop intelligently circuits and equipment to handle these data required first the development of a transmission measuring tool capable of operation at the high speeds involved. It is the purpose of this paper to describe an all-electronic, transistorized testing set which will measure bias distortion, characteristic distortion, and peak fortuitous distortion at transmission speeds from 200 to 1,400 bits per second.

Basic Principles

Distortion in binary pulse transmission may be defined as the deviation in length or relative time relationship of the received pulses from the length and time relationship of their transmission. A signal is defined as unbiased when the unit-marking and spacing pulses are of the same length or time duration. Bias distortion usually results from improper adjustment of terminal or circuit equipment. A means for measuring this type of distortion should be included in a data transmission testing set.

Distortion caused by electrical or magnetic characteristics of the equipment or circuit under test is defined as characteristic distortion. It is the amount by which a given pulse is lengthened, shortened, or displaced as a result of the presence or absence of neighboring pulses, and is caused by "memory" effects in the transmission path. More exactly, the maximum amount by which the space-to-mark and mark-to-space transitions of a selected pulse are shifted from their ideal locations by the presence or absence of neighboring pulses is a measure of the characteristic distortion. A device to measure characteristic distortion might then consist of a pulse pattern generator for sending various combinations of marking and spacing pulses, a circuit for selecting one of the received pulses for examination, and a circuit for comparing the distorted received pulse with the undistorted transmitted pulse to indicate the amount of distortion. The characteristic distortion would be taken as the largest value indicated for all possible combinations of pulses from the pattern generator.

Fortuitous distortion is that displacement of signal transitions resulting from extraneous electrical interference in the transmission circuit. This interference is statistical in nature and has a random relation to the testing signals. The "instantaneous" distortion caused by fortuitous interference will vary widely although the "average" effect on a repeated pulse will integrate to zero. It is conventional to measure fortuitous distortion as the largest transition displacement encountered in a given period. The measurement of fortuitous distortion should not be influenced by the characteristic distortion of the circuit under test. A device to measure fortuitous distortion might then consist of a pattern generator for sending alternate marking and spacing pulses of equal length, a circuit for selecting one of the pulses for examination, and a peak-reading instrument for measuring the largest transition displacement during the period of observation.

Description

In contrast to telegraph codes, data codes have not yet been standardized as to transmission speeds or number of code elements per character. For the design of a testing set, a code of ten elements and speeds from 200 to 1,400 bits per second was selected arbitrarily.

A block diagram of the testing set is shown in Fig. 1. It is completely transistorized except for two magnetron beam-switching tubes and a subminiature electrometer tube. Both transmitter and receiver sections are controlled by the output of a 200- to 1,400-cycle sine wave oscillator adjustable in steps of 200 cycles. The oscillator frequency enters the transmitter section through a squaring amplifier. The square wave from this amplifier is then differentiated and the resultant pulses used to trigger a standard bistable flip-flop stage. Because the flip-flop reverses once per cycle of the applied frequency, its output is a highly symmetrical or unbiased square wave, i.e., the time duration of the negative and positive loops are equal. Two appropriately phased outputs from the flip-flop drive the odd and even grids respectively, of a 10-position beam-switching tube to advance the beam one position for each reversal of the flip-flop. A 10-position signal pattern selector switch associated with the beam-switching tube permits any one of ten signal patterns to be selected for transmission at a bit rate equal to the oscillator frequency in cycles per second.

The adjustable oscillator also operates a second beam-switching tube in the receiver portion of the test set so that both tubes run at exactly the same speed. The drive circuit for the receiver tube includes a continuously adjustable phase shift network of a 360-degree range. This network, in conjunction with a phase switch associated with the beam-switching tube, permits a gate pulse and a reference pulse, to be obtained once per revolution, which may be placed in any desired time relationship with the transmitter signal pattern. These pulses have precisely the same length as the transmitter pulses. The gate pulse selects the leading or trailing portion of a given signal pulse to be measured by means of the coincidence circuit. The output of the coincidence circuit is applied to the characteristic distortion meter circuit, where it is compared with the reference pulse for characteristic or bias distortion measurements. To measure peak fortuitous distortion, the output of the coincidence circuit is applied to the fortuitous distortion meter circuit.

Ten signal patterns each consisting of ten bits are available for transmission, as indicated in Fig. 2. The polarity of transmission may be shown or reversed

as desired. After transmission through the circuit or equipment under test, pulse *9* is normally used for characteristic distortion analysis. The signal patterns have been selected to include combinations producing the maximum distortion of pulse *9* that could occur with normal random message traffic.

Bias and Characteristic Distortion Measurement

A circuit for the selection of the leading or trailing portions of a received signal pulse for bias or characteristic distortion measurement is shown in Fig. 3. After transmission over the system under test, the signals enter a coincidence circuit at *A*. A gate pulse from the receiver beam-switching tube is selected by means of the phase switch, and it enters at *B*. Transistors *Q1* and *Q2* comprise a coincidence circuit, and transistors *Q3*, *Q4*, and 50-0-50 scale meter comprise a differential metering circuit. The output of the coincidence circuit enters the metering circuit through transistor *Q3* and a reference pulse from the receiver beam-switching tube enters through transistor *Q4*. Because the pulses are applied differentially to the meter, a zero reading will result when the pulses have equal areas. The manner in which the amount of bias or characteristic distortion is indicated is illustrated in Fig. 4. Bias measurements are made on a-c signals, signal pattern *2*, position *2*, of the signal pattern selector switch. Any pulse of the pattern may be selected for bias distortion measurements but pulse *9* is used for characteristic distortion measurements. It is necessary to measure the displacement of the leading transition and the trailing transition of the pulse with respect to their undistorted positions, in order to determine the amount of distortion. These transitions are measured separately, as indicated in Fig. 4. The received a-c signal pattern is shown at *A*. If these signals are unbiased they will have exactly the same length as the gate pulse from the receiver beam-switching tube shown at *B*. The gate pulse may be made to straddle either the leading or the trailing edge of a received pulse by means of the phase switch and the adjustable phase shifter included in the receiver beam-switching tube drive circuit.

The output of the coincidence circuit is shown at *C* and the reference pulse at *D*. The length of the *D* pulse is exactly the same as that of the *B* pulse but its amplitude is made to be precisely one half the amplitude of the *C* pulse. By properly adjusting the phase of gate pulse *B*, the *C* pulse for the leading transition of signal pulse *9* can be made exactly the same length as the *C* pulse for the trailing transition of the pulse *9* so that both *C*

pulses have the same length and area. If the signals are unbiased, both *C* pulses are also equal in area to reference pulse *D*. Since the *D* pulse and a *C* pulse are applied alternately and differentially to the zero center d-c meter, a zero reading of the meter will result. If the received signals at *A* are biased, the length of the *C* pulses for the leading and trailing edges will still be equal. However, the *C* pulses will be greater or smaller in area than the *D* pulse, depending on whether the bias is marking or spacing, and the differential meter will indicate directly the direction and magnitude of the bias in per cent of the duration of an undistorted pulse.

An integrating condenser in the differential meter circuit produces a steady meter reading by eliminating the effects of fortuitous interference. A bias measurement is made by alternately switching between two adjacent positions of the phase switch, to select alternately the leading and trailing transitions, simultaneously adjusting the phase shift network for the same meter reading.

Before characteristic distortion measurements can be made, all bias should be removed from the signals to be measured, by the procedure just described to indicate the unbiased condition. As previously stated, characteristic distortion is measured by selecting signal pulse *9*, and observing the displacement of the leading and trailing transitions for the various signal patterns. The displacements are measured relative to the location of the leading and trailing transitions for signal pattern *2* (a-c).

Pulse *9* is selected for measurement by transmitting signal pattern *3*, consisting of a single pulse in position *9*. If gate pulse *B*, Fig. 4, is coincident with any other pulse position than position *9*, the differential meter will read −50% distortion, since only reference pulse *D* is applied to the meter circuit. The leading edge of pulse *9* is located by rotating the phase switch in a clockwise direction until the meter reads other than −50%.

The meter reading is a direct measurement of the leading edge displacement in per cent of the length of an undistorted pulse. This reading may be converted to time if desired since the pulse transmission rate is accurately known. If the leading edge is not affected by characteristic distortion, it will have the same location as for pattern *2* (a-c), and the meter will read zero. The displacement of the trailing edge may similarly be measured by rotating the phase switch to the next adjacent clockwise position. In such fashion the displacement of the transitions are measured for signal patterns *3* through *10*. The amount of characteristic distortion for the particular transmission speed is taken as the largest meter reading of the series. To delineate this distortion characteristic completely, measurements must be made for a range of speeds. Typical curves of distortion versus speed measured in a medium-speed data channel are given in Fig. 5. The effect of speed on the leading transition of pulse *9* for pattern *3*, and the trailing transition of pulse *9* for pattern *6* are clearly shown.

FORTUITOUS DISTORTION MEASUREMENT

Fortuitous distortion displaces the leading and trailing transitions of a signal pulse in a random manner. It is

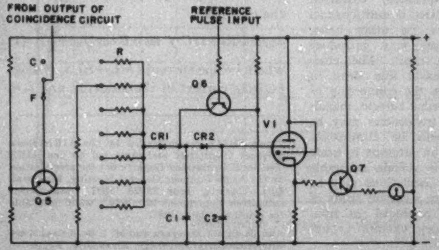

Fig. 6 (left). Peak fortuitous distortion measuring circuit

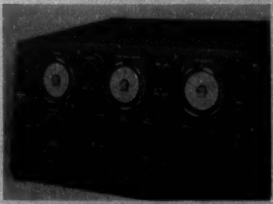

Fig. 7 (right). Data transmission testing set, front view customary to measure the greatest displacement occurring in a specified time interval and to define this value as the peak fortuitous distortion of the circuit or equipment under test. Fortuitous distortion measurements are made on a-c signals, signal pattern 2, to eliminate any meter deflection caused by characteristic distortion. The signals must also be checked for bias and corrected if necessary.

The circuit used to measure peak fortuitous distortion is illustrated in Fig. 6. Pulses from the coincidence circuit are applied to transistor *Q5*, and the reference pulses from the receiver beam-switching tube to transistor *Q6*. The fixed amplitude pulse from the coincidence circuit is applied to integrating capacitor *C1* through a resistor and diode *CR1*. Capacitor *C1* charges to a voltage directly proportional to the time duration of the pulse and is bound by the action of diode *CR1*. Capacitor *C2*, which is small compared to *C1*, charges through diode *CR2* to the same value as *C1*. The reference pulse from the receiver-switching tube discharges *C1* by driving transistor *Q6* to conduction leaving a bound charge on *C2*.

If the next pulse from the coincidence circuit is longer than the preceding pulse because of fortuitous distortion, capacitor *C1* will charge to a higher value, as will capacitor *C2*. In this manner a charge is accumulated on *C2* proportional to the largest displacement of the pulse transition. The voltage of capacitor *C2*, resulting from its accumulated charge, is measured by electrometer tube *V1*. The plate current of *V1* is thus a measure of the widest pulse occurring during the measuring period. This current is amplified by transistor *Q7* and displaced on a 0 to 40 scale meter calibrated to indicate distortion in per cent of the length of an undistorted pulse. Both the leading and trailing transitions are measured, the larger of the two being the peak fortuitous distortion for the particular speed of transmission. Calibration is maintained for different speeds by the automatic selection of the proper charging resistor *R* for a given signaling speed.

Results

A prototype model of the transmission testing set is shown in Fig. 7. This model was constructed for laboratory use only and requires that both ends of a transmission circuit be available in order to permit measurements to be performed. Models for field use would require a highly stable frequency source to permit accurate synchronization and phasing of units at the ends of the intervening circuit being tested. The prototype has been in use for several months and has proved of valuable assistance in the development of data transmission circuits and equipment, particularly in studies concerning the effect of envelope delay distortion on high-speed data transmission.

Subharmonics in Iron-Cored Reactor Oscillatory Circuits

ABD EL-SAMIE MOSTAFA
NONMEMBER AIEE

M. I. EL-KARAKSI
NONMEMBER AIEE

Synopsis: This report gives a careful study of subharmonic sustained oscillations found in iron-cored reactor oscillatory circuits. The analysis is based on the power balance principle, giving satisfactory explanation and understanding of the idea of frequency conversion. The analysis is valid for both the harmonic and subharmonic cases. The ranges of synchronization, the methods of starting, and the conditions of stability of these oscillations are given. Numerical examples for the third subharmonic oscillations are presented. Just outside the locking range, the amplitude and phase of the subharmonic oscillations are no longer constant, but variable; the oscillations are defined as "pulled oscillations." A theoretical analysis for determining the instantaneous phase angle is given. An experimental investigation to test the validity of the theoretical analysis is carried out. The experimental work includes steady and transient conditions, a harmonic source of voltage being applied. The ranges of the supply voltage switching angles required for starting sustained oscillations for different circuit parameters are experimentally obtained. An initial charging of the condenser or an instantaneous application of d-c flux improves the starting conditions.

Subharmonic oscillations generated in oscillatory circuits containing iron-cored reactors have found increasing use in electrical engineering. The production of the 20- or $16^2/_3$-cycle ringing current from the 60- or 50-cycle power respectively, is a commercial application. A static frequency divider which is well stabilized and easily operated is suggested; frequency standardization is a good application of such a frequency divider. When operated at high supply frequencies, sustained oscillations may be utilized in multichannel carrier telephony. On the other hand, subharmonic oscillations may introduce difficulties in certain cases. The compensation of transmission line drop in power circuits requires the connection of series capacitors, abnormal current magnitudes of submultiple frequencies may be produced; these should be eliminated. In general, whenever an attempt is made to tune circuits which include saturable reactors, subharmonic oscillations may be encountered. Therefore a careful study of sustained oscillations produced in iron-cored reactor oscillatory circuits is important.

THE circuit to be analyzed is the simple series oscillatory circuit shown in Fig. 1, where ϕ represents the flux linkage of the iron-cored reactor, including any leakage flux; R is a load resistance including the winding resistance of the reactor coil; and C is a capacitor. A harmonic source of voltage $e_s[=E\cos(\omega_s t+\alpha)=E\cos(m\omega t+\alpha)]$ is applied to the circuit, where $\omega_s/2\pi=m\omega/2\pi=$ supply frequency, and m is an integer. Both hysteresis and eddy current losses may be approximately represented by a constant resistance r shunting the inductor.

Fig. 2 shows the d-c $\phi\rightarrow i_\phi$ characteristic of the iron-cored reactor used. It was found more appropriate to represent the characteristic by a power series; thus

$$i_\phi=a_1\phi+a_3\phi^3+a_5\phi^5+\ldots$$

The differential equation for the current in the circuit is

$$d\phi/dt+Ri+1/C\int i\,dt=E\cos(\omega_s t+\alpha) \quad (1)$$

where $i=$ line current $(=i_\phi+i_r)$, $i_\phi=$ magnetizing current of the inductor, and $i_r=$

Paper 57-745, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Summer General Meeting, Montreal, Que., Canada, June 24–28, 1957. Manuscript submitted September 13, 1954; made available for printing July 9, 1957.

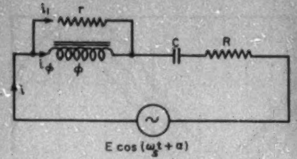

Fig. 1. Ferro-resonant series circuit

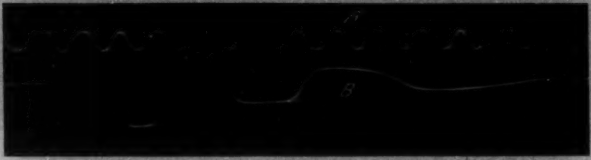

Fig. 3. Oscillogram giving free decayed charge across capacitor in iron-cored reactor oscillatory circuits

A—Timing wave 50 cycles
B—Charge waveform during decay

current representing the iron loss in the reactor $= (1/r)(d\phi/dt)$.

Substituting and rearranging, equation 1 becomes

$$d\phi/dt + E_{eq} i_\phi + (1/C_{eq}) \int i_\phi dt = E_{eq} \cos(\omega_s t + \alpha) \quad (2)$$

where

$$R_{eq} = [1/(1+R/r)][R + (\phi/i_\phi)/rC]$$
$$C_{eq} = C[1+R/r]$$
$$E_{eq} = E/(1+R/r)$$

To produce sustained subharmonic or harmonic oscillations, energy must be transferred from the voltage source to the oscillation at the right instant and in the right direction; in other words, the oscillation must be in some form of synchronization with the supply. If the supply voltage e_s is absent, damped free oscillation takes place with a frequency which decreases as the amplitude decreases, the condenser being assumed initially charged; see Figs. 3, 4, and 5. However, if e_s is applied, both free and forced oscillations take place. If the frequency of the free oscillation, being dependent on the amplitude, is near $n\omega/2\pi$ (n being an integer), energy is transferred from the voltage source to the free oscillation resulting in disturbing the phase angle between the oscillation and the applied voltage. If a state is reached in which the phase balance of the oscillation can be maintained at the frequency $n\omega/2\pi$, the oscillation can be sustained. Such sustained oscillation is therefore synchronized oscillation.

Neglecting the harmonics of both forced and synchronized oscillations, the flux ϕ of equation 2, at the steady state, may be assumed to be of the following form

$$\phi = \phi_m \cos m\omega t + \phi_n \cos(n\omega t + \theta) \quad (3)$$

This assumption is satisfactory as the circuit is resonating at nearly the frequency of the synchronized oscillation. Substituting equation 3 in the $i_\phi \rightarrow \phi$ series gives

$$i_\phi = \Sigma K_{k,\pm h} \cos[(km \pm hn)\omega t \pm h\theta] \quad (4)$$

In equation 4, the summation is made for $k=0, 1, 2, 3$, etc., $h=0, 1, 2, 3$, etc., k different from h, and $(k \pm h)$ odd. The upper limit of the summation depends on the number of terms in the $i_\phi \rightarrow \phi$ series. The constants $K_{k,\pm h}$ are functions of ϕ_m, ϕ_n as well as coefficients a_1, a_3, a_5, etc.

Transfer of Active Power Through the Coil

As the power in the coil is equal to the mean value of $\int v i_\phi \, dt$, and v is the voltage across the reactor and equal to $d\phi/dt$, the current components responsible for the active power P_c in the coil must be of the form $[M \sin m\omega t + N \sin(n\omega t + \theta)]$, which can be selected from equation 4. Carrying out this process gives

$$P_c = P_{c_m} + P_{c_n} \quad (5)$$

where

P_{c_m} = power given to coil at the supply frequency $m\omega/2\pi$

$$= -\frac{1}{2} m\omega\phi_m \sum_{(k-1)m = \mp hn} \mp K_{k,h} \sin h\theta \quad (6)$$

and

P_{c_n} = power given to coil at the synchronized oscillation frequency $n\omega/2\pi$

$$= -\frac{1}{2} n\omega\phi_n \sum_{km = (1 \mp h)n} \mp K_{k,h} \sin(h \mp 1)\theta \quad (7)$$

With equations 6 and 7, it may be shown that the sum of P_{c_m} and P_{c_n} is zero. This conclusion is natural since the coil dissipates no energy. The coil derives

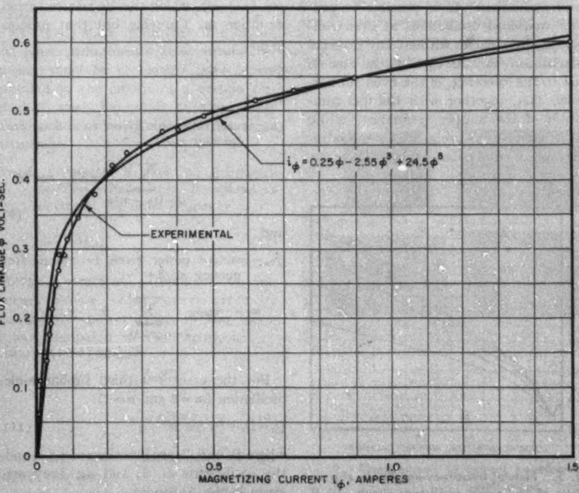

Fig. 2. Representation of magnetization curve

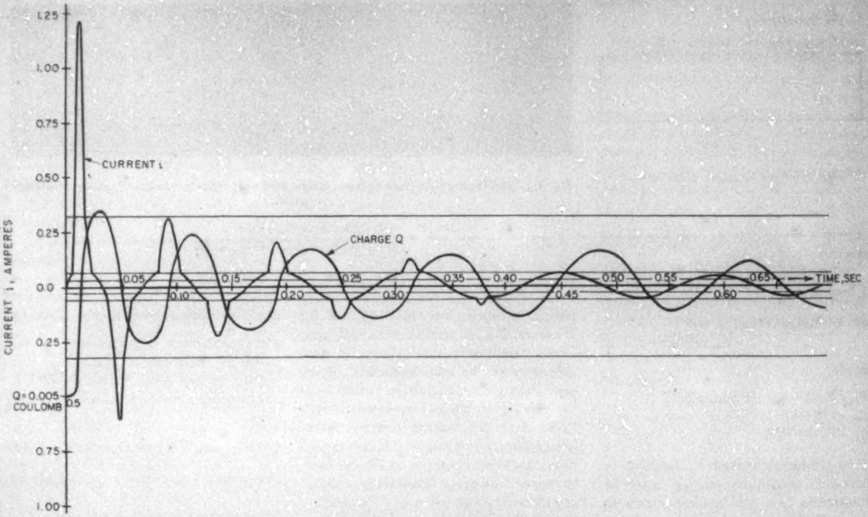

Fig. 4. Theoretical current and charge waveforms during decay in iron-cored reactor oscillatory circuit. C=100 μf, R=10 ohms, initial charge on condenser=0.005 coulomb

power from the supply at its frequency $m\omega/2\pi$ and delivers the same amount of power at another frequency $n\omega/2\pi$, i.e., the coil acts as a frequency converter.

If only three terms in the $i_\phi \rightarrow \phi$ series are considered, the expressions for P_{c_m} and P_{c_n} for different values of m and n may be easily obtained from equations 6 and 7 and are given by

1. Third subharmonic oscillation, $m=3$ and $n=1$:

$$P_{c_3}=D_1 \sin 3\theta=-P_c \tag{8}$$

2. Fifth subharmonic oscillation $m=5$ and $n=1$:

$$P_{c_5}=D_2 \sin 5\theta=-P_{c_1}$$

3. Third harmonic oscillation $m=1$ and $n=3$:

$$P_{c_1}=D_3 \sin \theta=-P_{c_3}$$

4. Second subharmonic oscillation $m=2$ and $n=1$:

$$P_{c_2}=D_4 \sin 4\theta=-P_{c_1}$$

where D_1, D_2, D_3, and D_4 are functions of ϕ_1, ϕ_3, and the coefficients a_1, a_3, and a_5 given in the Appendix. It is clear that maximum power converted in coil for these four cases takes place when $3\theta=\pi/2$, $5\theta=\pi/2$, $\theta=\pi/2$, and $4\theta=\pi/2$ respectively.

In general, the converted power depends on the phase angle θ between the flux having the supply frequency and that of the sustained oscillation. This phase angle depends on the amount of detuning between the natural frequency of the circuit and the frequency of the synchronized oscillation. It is possible to generate sustained oscillations at even submultiple frequencies without any external polarization to the core as in case 4. Due to the presence of the even subharmonic flux, together with the flux component of the supply frequency, a d-c flux component is produced, which is responsible for the polarization of the core.

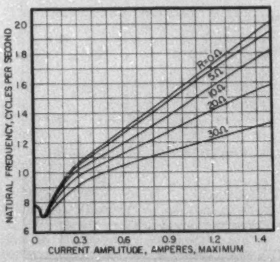

Fig. 5. Natural frequency-amplitude characteristic of iron-cored oscillatory circuit with R as parameter

Reactive Power in Coil

It is clear that the current components responsible for the reactive power Q_c in the coil must be of the form $A \cos m\omega t+B \cos (n\omega t+\theta)$, which can be selected from equation 4. Carrying out that process gives

$$Q_c=Q_{c_m}+Q_{c_n}$$

where

Q_{c_m} = reactive power given to coil at frequency $m\omega/2\pi$

$$=-\frac{1}{2} m\omega\phi_m \sum_{(h-1)m=\mp hn} \pm K_{k,h} \cos h\theta \tag{9}$$

and

Q_{c_n} = reactive power given to coil at frequency $n\omega/2\pi$

$$=-\frac{1}{2} n\omega\phi_n \sum_{km=(1\mp h)n} \pm K_{k,h} \cos (h\mp 1)\theta \tag{10}$$

For the case of a third subharmonic oscillation ($m=3$ and $n=1$)

$$Q_c=D_5+D_6 \cos 3\theta \tag{11}$$

where D_5 and D_6 are functions of ϕ_1, ϕ_3 and the coefficients a_1, a_3 and a_5; they are given in the Appendix.

As stated before, power converted in

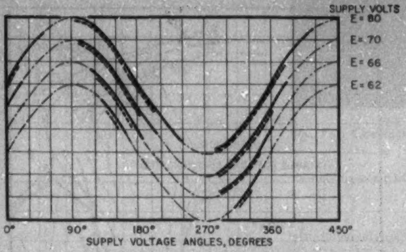

Fig. 6. Ranges of supply voltage switching angles at which third subharmonic sustained oscillations may be started for different values of resistance R and supply voltage E, C=100 μf, —— R=10 ohms, - - - R=20 ohms

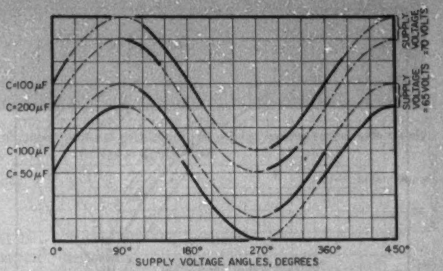

Fig. 7. Ranges of supply voltage switching angles at which third subharmonic sustained oscillations may be started for different values of capacitance C and supply voltage E. R=10 ohms

coil is maximum when $3\theta=\pi/2$, in which case the amount of detuning is equal to zero. If there is some detuning in the system, there must be an additive reactive power taken from the supply through the conversion in the coil in order to keep the system in a synchronized state. This reactive power constitutes the terms containing $\cos 3\theta$ in equation 11.

Quantitative Evaluation of Sustained Oscillation

With the conception that the coil could be considered as a frequency-converter-source, quantitative evaluation of the sustained oscillations may be determined.

At steady-state conditions, the different power components at a certain frequency must be in balance, i.e., power supplied to the circuit at a certain frequency must be equal to the power dissipated in the circuit at the same frequency.

Power generated in coil at frequency $n\omega/2\pi=-P_{c_n}=$power dissipated in circuit at the same frequency

$$=\frac{1}{2}I_n^2R_{eq} \tag{12}$$

where $I_n=$current component of frequency $n\omega/2\pi$. Also, power given by the supply=power given to the coil+power dissipated in the circuit, i.e.,

$$\frac{1}{2}E_{eq}I_m\cos\alpha=P_{c_m}+\frac{1}{2}I_m^2R_{eq}$$

$$=\frac{1}{2}(I_m^2+I_n^2)R_{eq} \tag{13}$$

where $I_m=$current component of the supply frequency.

Again, for steady-state operation, the sum of the reactive powers in the circuit at a certain frequency must vanish; therefore reactive power at frequency $n\omega/2\pi=$reactive power in coil+reactive power in condenser

$$=Q_{c_n}-\frac{\frac{1}{2}I_n^2}{n\omega C_{eq}}=0 \tag{14}$$

and reactive power at a frequency $m\omega/2\pi=0$, giving reactive power in coil+reactive power in condenser=reactive power delivered by the supply, i.e.

$$Q_{c_m}-\frac{\frac{1}{2}I_m^2}{m\omega C_{eq}}=\frac{1}{2}E_{eq}I_m\sin\alpha \tag{15}$$

Using equations 12, 13, 14, and 15, together with the relations of R_{eq}, C_{eq}, and E_{eq}, the values of ϕ_m, ϕ_n, θ, and α may be obtained for given values of E, C, R, and a certain iron-cored reactor.

Conditions of Stability of Oscillations

With the aid of equations 12, 13, 14, and 15, the stationary amplitudes and phase of the sustained oscillation may be obtained; whether these values occur in practice or not depends on their stability.

Active power at a frequency $(n\omega/2\pi)$ is derived from the coil through convetsion, as stated before, and is equal to $-P_{c_n}$. Also, power lost in circuit at the same frequency $n\omega/2\pi$ is equal to $(1/2)I_n^2R_{eq}$. At the stationary state, these two powers are equal; see equation 12. However, due to any slight disturbance in the system, the balance in power is disturbed and there will be a net power. Thus

$$-P_{c_n}-(1/2)I_n^2R_{eq}=\text{net power at a frequency } n\omega/2\pi=P_{net} \tag{16}$$

For the oscillation to be stable, any

slight increase ΔI_n, in its stationary amplitude, must be accompanied by a decrease ΔP_{net} in the net power; otherwise the amplitude would rise indefinitely. Therefore the condition of stability is that $\Delta P_{net}/\Delta I_n$ must be negative at the stationary values, i.e.,

(dP_{net}/dI_n) (at the stationary values)<0, or
$(d(P_{net}/I_n^2)/dI_n)$ (at the stationary values) <0

Using equation 16 gives

$$d(P_{net}/I_n^2)/dI_n = d(-P_{c_n}/I_n^2)/dI_n$$

Substitution in the inequality gives the condition of stability, namely

$$[d(-P_{c_n}/I_n^2)dI_n] \text{ (at the stationary values)}<0 \qquad (17)$$

Methods of Starting Oscillations

A free oscillation may be sustained if its amplitude attains such a value that the natural frequency of the circuit is near $n\omega/2\pi$. Although this is a fundamental condition, it is not sufficient because the phase angle between the free oscillation and the supply voltage must be within certain limits in order that the former may be pulled in and hence sustained. The natural frequency depends fundamentally on the current or charge amplitude; see Figs. 3, 4, and 5. Therefore the initial amplitude of oscillation is an important factor in determining the possibility of producing sustained oscillations. This amplitude depends on initial conditions, namely

1. Supply voltage switching angle, i.e., the magnitude of the supply voltage at the instant of energizing the circuit.
2. Initial charge on the condenser.
3. Initial flux linkage of the iron-cored inductor.

There is a range of supply voltage switching angles in which the free oscillations may be synchronized and hence sustained; see Figs. 6 and 7. These last two figures are practically obtained by closing the circuit at certain supply voltage switching angles with the use of a synchronous-relayed switch; the relay being preset so that the switch permanently closes the circuit when the current reaches the value of the required sustained oscillation. It is clear from Fig. 6 that, for a given capacitance, the range of the supply voltage switching angles increases as the supply voltage increases and as the circuit resistance decreases. Therefore, for starting by direct switching, the supply voltage should be increased to the maximum value at which sustained oscillations are possible and the circuit resistance decreased to the minimum possible value. It is again clear from Fig. 7 that for the same supply voltage the range of the supply voltage switching angles may be increased by reducing the capacitance. These characteristics of the circuit may be analyzed as follows.

For the same supply voltage and capacitance, an increase of the resistance leads to a decrease of the first maximum amplitude of oscillation, and hence the range of supply voltage switching angles decreases. Increasing the supply voltage is in certain respects equivalent to a decrease in circuit resistance, and hence the increase of supply voltage will increase the supply voltage switching angles. For the same supply voltage and the same resistance, an increase of capacitance necessitates a reduction in the effective inductance of the circuit to have a third subharmonic oscillation; the first maximum amplitude of oscillation must therefore be increased, and hence the range of the supply voltage switching angles decreases.

The range of the supply voltage switch-

B—Current wave

ing angles may be increased by either charging the condenser or applying instantaneously a polarizing flux prior to energizing the circuit. In this way the first maximum amplitude of the charge can attain any value independent of the supply voltage switching angle. Experiments showed that, with a reasonable initial charge, 1 out of 50 switching operations fails to produce sustained oscillations at one third of the supply frequency. Starting by applying instantaneously a d-c flux yields even better results. If the d-c flux is not only instantaneously applied but permanently kept in the core, sustained oscillations, especially those of even subharmonics (one half and one fourth the supply frequency, for example) are produced whatever the switching angle may be. With permanent polarizing flux linkage, the frequency of the sustained oscillations may be varied with variation of the magnitude of the polarizing current. Sustained oscillations of frequencies one fifth, one fourth, one third, and one half the supply frequency are obtained experimentally by only varying the polarizing current. In this way, the system is considered as a variable frequency divider. As a practical application, a static, easily operated and stabilized frequency divider is suggested operating at different spot frequencies.

It should be noted here that the waveforms of the sustained oscillation of a certain order (one third the supply frequency, for example) are independent of the supply voltage switching angle, the circuit parameters (R, C, and E) being the same; they are generally independent of the method of starting whether it is initially charging the condenser or applying instantaneously a d-c flux in the core. However, in case there is a permanently polarizing d-c flux the waveforms will not be skew symmetrical. Fig. 8 shows several oscillograms for the second, third, fourth and sixth subharmonic currents with and without a polarizing flux. The first maximum amplitude of the charge on the condenser depends on the supply voltage switching angle, the condenser being initially uncharged.

Numerical Calculations for Sustained Oscillations of One Third the Supply Frequency

One of the cases investigated experimentally will be calculated. The ranges of synchronization, the limiting values of the supply voltages, and the conditions of stability will be estimated. The magnetization curve of the iron-cored reactor used is that shown in Fig. 2, and which is represented by the following equation

$$i_\phi = 0.25\phi - 2.55\phi^3 + 24.5\phi^5 \qquad (18)$$

where i_ϕ is the current in amperes, ϕ the flux linkage in volt-seconds, and the representation is valid up to $i_\phi = 1.5$ amperes.

It is found experimentally that the iron loss resistance r has an average value of 2,750 ohms while the possible ranges of the series resistance R are up to 60 ohms, and the quantity $(1+R/r)$ is very near unity; therefore E and C can stand satisfactorily for E_{eq} and C_{eq} respectively. To simplify calculations, the average value of ϕ/i_ϕ, in the whole operating ranges, is used instead of ϕ/i_ϕ in the expression of R_{eq}. Again, it was found that this average value is approximately equal to 1.0 and thus $(\phi/i_\phi)/rC$ is small and R can stand satisfactorily for R_{eq}.

Assume the initial conditions and the different circuit parameters which are C, R, and E to be such that the sustained oscillations are of one third the supply frequency. Let the flux linkage be of the form

$$\phi = \phi_3 \cos 3\omega t + \phi_1 \cos(\omega t + \theta)$$

where $\omega/2\pi$ = frequency of the sustained oscillation, and $3\omega/2\pi$ = supply frequency.

Substitution in equation 18 gives

$$i_\phi = A_1 \cos 3\omega t + A_2 \sin 3\omega t + B_1 \cos(\omega t + \theta) + B_2 \sin(\omega t + \theta) + \text{components of frequencies other than } 3\omega/2\pi \text{ and } \omega/2\pi \qquad (19)$$

where A_1, A_2, B_1, and B_2 are functions of ϕ_1, ϕ_3, and θ, and given in the Appendix.

From equation 8

$$P_{e_3} = \text{power in coil at supply frequency} = \frac{1}{2}\omega\phi_3\phi_1^3[1.9125 + 47.188(\phi_3^2 + (1/2)\phi_1^2)] \sin 3\theta = -P_{e_1}$$

Using equations 12 and 13 yields

$$P_{e_1} = \text{power in coil at the subharmonic frequency } \omega/2\pi = \text{power dissipated in the circuit at the same frequency} = \frac{1}{2} I_1^2 R = \frac{1}{2}(B_1^2 + B_2^2)R \qquad (20)$$

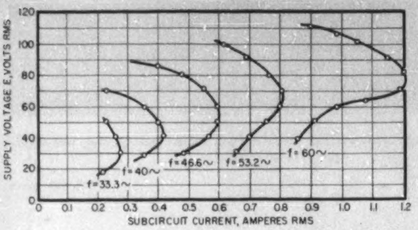

Fig. 14. Experimental synchronizing ranges of third subharmonic oscillations. C=100 μf, R=10 ohms

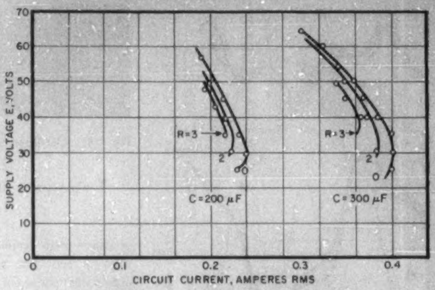

Fig. 15. Experimental synchronizing ranges of fifth subharmonic oscillations

and

$$(1/2)EI_3 \cos \alpha = \frac{1}{2}(I_1^2+I_3^2)R \tag{21}$$

where

$$I_3 = (A_1^2+A_2^2)^{1/2}$$

Again, equations 14 and 15 give

$$Q_{c_1} - \frac{1}{2} I_1^2/\omega C = 0 \tag{22}$$

and

$$Q_{c_3} - \frac{1}{2} I_3^2/3\omega C = \frac{1}{2} EI_3 \sin \alpha \tag{23}$$

where

Q_{c_1} = reactive power in coil at frequency $\omega/2\pi$

$= \frac{1}{2}\omega\phi_1 B_1,$

and

Q_{c_3} = reactive power in coil at frequency $3\omega/2\pi$

$= -\frac{3}{2}\omega\phi_3 A_1$

Eliminating α between equations 21 and 23 gives

$$Q_{c_3} - (1/2)I_3^2/3\omega C = \pm(1/2)[E^2I_3^2 - (I_1^2+I_3^2)^2R^2]^{1/2} \tag{24}$$

From equations 20, 22, and 24 complete information about the third subharmonic oscillation may be graphically obtained, aided generally with auxiliary curves.

Fig. 9 shows the relation between E and $(I_1^2+I_3^2)^{1/2}$ for different values of R and for C=100 μf (microfarads) giving the different ranges of synchronization, E being variable. Lines of constant 3θ are shown in the same figure in dashed lines. It is clear from Fig. 9 that a synchronization curve covers a range of the angle 3θ which decreases as R increases. The relation between E and $(I_1^2+I_3^2)^{1/2}$ for R=0 represents at the same time the two constant 3θ–lines for 3θ=0 and 180 degrees. With the use of equation 17 and aided with auxiliary curves, the regions of stability are obtained; see Fig. 10.

It should be noted here that the discontinuity in the synchronizing ranges for low values of resistances, Figs. 10 and 11, is due to instability. This can be physically attributed to the fact that at such a portion of the curve the amount of detuning is large and this is why it occurs at low values of resistances. The smaller the resistance the larger the variation of natural frequency with amplitude; Fig. 5.

To check the validity of the theoretical predictions regarding the amplitudes and phases of the different components constituting the wave of the sustained oscillations, one of the experimental cases, namely E=62 volts (maximum), C=100 μf, and R=30 ohms, is calculated, giving the following values:

Supply voltage e_s=62 cos ($3\omega t$+58 degrees 46 seconds)
Line current i=0.447 cos $3\omega t$+0.543 cos (ωt+31 degrees 30 seconds)
Flux linkage ϕ=0.217 cos ($3\omega t$+15 degrees) +0.545 cos (ωt+48 degrees 20 seconds)
Voltage across capacitor v_c=14.2 sin $3\omega t$+51.9 sin (ωt+31 degrees 30 seconds)
Voltage across reactor=v=−68.2 sin ($3\omega t$+15 degrees)−57 sin (ωt+48 degrees 20 seconds)

The theoretical waveforms are shown by dashed lines on the corresponding experimental oscillograms, Fig. 12, indicating satisfactory agreement.

Oscillations Just Outside the Locking Range

It was found experimentally that just outside the locking range, the subharmonic oscillations may exist but with slowly varying amplitudes and phases; see the oscillogram of Fig. 13. Just outside the locking range, a change takes place in the instantaneous rate at which energy is supplied from the voltage source to the oscillatory circuit. This results in disturbing the phase balance of the subharmonic oscillation with a subsequent change in frequency. The con-

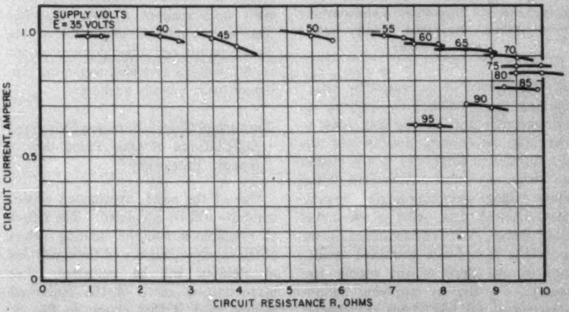

Fig. 16. Experimental synchronizing ranges of second subharmonic oscillations

tribution of the voltage source to the instantaneous rate of energy supplied favors any oscillation of a frequency nearer $n\omega/2\pi$ and thence pulling takes place. The oscillations may therefore be defined as "pulled oscillations." They can be considered as harmonic or subharmonic oscillations but modulated in both amplitude and phase.

In the following analysis, it is assumed that the variation in the amplitude of the flux linkage of the subharmonic oscillation is very small and neglected. This assumption is experimentally satisfied in most cases.

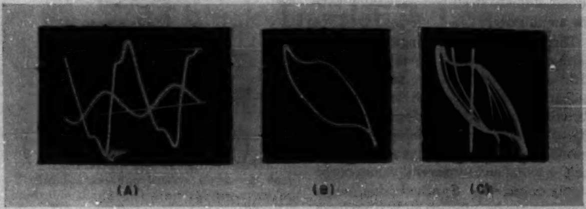

Fig. 17. Lissajous figures of third subharmonic oscillation indicating that subharmonic oscillations should build up in synchronized state. Cartesian waveforms at steady state also indicated

A—Cartesian waveforms B—Steady state C—Building up

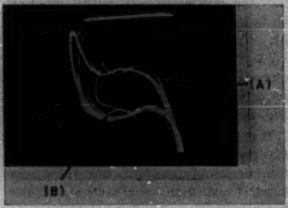

Fig. 18. Lissajous figure indicating that oscillation starts freely and continues for about 2 cycles of natural frequency and then pulls in and continues synchronized until steady state

A—Start
B—Instant of pulling in

Consider the pulled oscillations just outside the third subharmonic locking range and let the flux linkage be given by $\phi=\phi_1 \cos\int(\omega+\theta')dt+\phi_3 \cos 3\omega t$, where θ' stands for $d\theta/dt$ and θ is a variable phase angle; $(\omega+\theta')$ is the instantaneous angular frequency.

Differentiating ϕ once and twice, and substituting in equation 2, after differentiating, yields equation 28 containing

$$\theta', \theta'', \theta'^2$$

$$\begin{matrix}\sin\\ \cos\end{matrix}\int(\omega+\theta')dt$$

$$\begin{matrix}\sin\\ \cos\end{matrix}\,3\theta$$

$$\text{and}\ \begin{matrix}\sin\\ \cos\end{matrix}\,3\omega t$$

where $\theta''=d^2\theta/dt^2$

Usually θ' is very slowly varying compared with ω so that θ'' and θ'^2 may be neglected. At the same time, θ' might be considered constant during an interval covering several cycles of oscillation. Therefore the coefficients of $\cos\int(\omega+\theta')dt$, $\sin\int(\omega+\theta')dt$, $\cos 3\omega t$, and $\sin 3\omega t$ might be separately equated with zero during this interval. Equating coefficient of $\cos\int(\omega+\theta')dt$ with zero, and rearranging, gives

$$d\psi/dt=k_1\,(1+k_2 \sin\psi) \tag{25}$$

where

$$\psi=3\theta-\beta,\ \tan\beta=(1/\omega C_{eq}R_{eq})(D+G)/(D-G)$$
$$k_1=(3/2)\omega[(1/\omega^2C_{eq})(A/\phi_1)-1]$$
$$k_2=(3/2k_1\phi_1)\{[(1/\omega C_{eq})(D+G)]^2+[R_{eq}(D-G)]^2\}^{1/2}$$

A, D, G are given in the Appendix.

Equation 25, although valid at the specified small interval of time, could be satisfactorily considered the general phase-frequency relation at any time t.

From the three relations resulting from equating the coefficients of $\sin 3\omega t$, $\cos 3\omega t$ and $\sin\int(\omega+\theta')dt$ separately with zero together with the solution of equation 25, ϕ_1, ϕ_3, θ, and α may be obtained for given E, C, R, and a certain iron-cored reactor.

Solution of equation 25 is

$$\tan[(3\theta/2)-\beta/2]=-k_2+(1-k_2^2)^{1/2}\tan[(k_1/2)(1-k_2^2)^{1/2}(t+t_0)] \tag{26}$$

where t_0 is a constant of integration.

It is clear from equation 26 that if $|k_2|<1$, θ is periodic and pulled oscillations result. However, if $|k_2|>1$, the tangent of the right-hand side of equation 26 will become a hyperbolic tangent, and θ will go asymptotically toward a constant value and the oscillations will be locked. The range of locking is therefore given by $k_2=\pm1$.

If $|k_2|<1$ (periodic case), then as time t goes on, $[(k_1/2)(1-k_2^2)^{1/2}(t+t_0)]$ passes through $\pi/2$, $3\pi/2$, $5\pi/2$, etc., and the tangent of the right-hand side of equation 26 passes through $+\infty$, $-\infty$, $+\infty$, etc., hence $[(3\theta/2)-(\beta/2)]$ will pass through $\pi/2$, $3\pi/2$, $5\pi/2$, etc. This means that 3θ possesses the same period as $k_1(1-k_2^2)^{1/2}t$. But, while $k_1\,(1-k_2^2)^{1/2}t$ increases uniformly with time, 3θ varies in a nonuniform manner. Therefore

$$\text{average rate of phase variation}=\theta'\,(\text{average})=(k_1/3)(1-k_2^2)^{1/2} \tag{27}$$

The apparent beat frequency is θ'(average), which is observed experimentally, between the oscillation under consideration and another signal of one third the supply frequency.

Very far from locking, k_2 approaches zero and θ' goes asymptotically toward $k_1/3$ and the oscillation will continue freely, but of course damped, with a frequency $[\omega+(k_1/3)]/2\pi$. As the system goes toward locking, the average frequency of oscillation $[=\omega+\theta'(\text{average})]$ will be shifted (pulled) away from the free frequency toward the locked frequency $\omega/2\pi$; see equation 27. This is again a reason for the resulting oscillations being defined as "pulled oscillations."

It is clear from equation 26 that the waveform of the instantaneous phase angle θ depends on k_1, k_2, and β, i.e., it depends on ϕ_1 and ϕ_3 and hence on the resistance R, the capacitance C, and the supply voltage E. It is also clear from equation 27 that the apparent beat frequency depends on ϕ_1 and ϕ_3 and hence on R, C, and E. Near locking, k_2 approaches unity and the period of θ' is very long so that the oscillations appear as if they were nonperiodic.

Experimental Investigation

To test the validity of the foregoing theoretical relations and conclusions regarding the analysis of sustained oscillations occurring in iron-cored reactor oscillatory circuits, as well as to investigate thoroughly the behavior of these oscillations, the following experimental work was carried out.

The magnetization curve passing through the tips of the magnetizing cycles, of the iron-cored reactor used in the experiments, is shown in Fig. 2. Since the natural frequency of the circuit plays a big role in the maintenance of the sustained oscillations, the freely decayed oscillations are recorded on a moving film; see Fig. 3. A 50-cycle timing wave was deliberately recorded on the same oscillogram for comparison. The oscillogram shows clearly that the frequency varies along the wave train; as the amplitude decreases, the frequency decreases. For the sake of comparison, theoretical waveforms of current and capacitor charge are shown in Fig. 4. The waveforms are calculated, representing the magnetization curve by four straight lines. Several other waveforms, for different values of R, are calculated. With these waveforms, the natural frequency against amplitude of oscillation for different values of R is obtained; see Fig. 5.

For the iron-cored reactor used in the experiments, sustained oscilllations of frequencies of one half, one third, one fourth, one fifth, one sixth, and one seventh the supply frequency are obtained. Fig. 11 shows the voltage-current characteristics of the third subharmonic oscillations for different values of capacitance and resistance and for a supply frequency of 50 cycles. For the purpose of comparison the theoretical as well as the experimental curves of the third subharmonic oscillations are shown in Fig. 10, indicating satisfactory agreement.

Fig. 14 shows the voltage-current characteristics for different values of supply frequency, the capacitance and the resistance are of values 100 μf and 10 ohms respectively. Fig. 15 shows the voltage-current characteristics of the fifth subharmonic oscillations for different values of C and R. It is clear from Figs. 11 and 15 that the ranges of synchronization decrease as the resistance increases.

It is also clear that the synchronizing ranges cover a larger current variation for larger capacities than for smaller ones and which is also observed in sustained oscillations of other subharmonic frequencies. These observations may be analyzed as follows.

For possible synchronization, the natural frequency of the circuit should not be far from the required subharmonic frequency; therefore as the capacity increases the effective inductance should be reduced, and hence the current should increase; see Fig. 11. The change of current for a given amount of effective inductance change increases as the current decreases; this is due to the saturation characteristic of the core. Therefore, for a certain amount of detuning between the natural frequency of the circuit and the frequency of the required subharmonic, the required change in current is higher the larger the condenser, agreeing with Figs. 11 and 15. For this reason, it is preferred from a design point of view to obtain sustained oscillations with large values of capacitance.

It should be noted that the synchronizing ranges extend for much larger variations in capacitance and frequency respectively than synchronization with electronic tubes; this is because the natural frequency of the iron-cored oscillatory circuit adjusts itself automatically with the amplitude.

The synchronizing ranges for subharmonics other than the third and the fifth are comparatively small. Even subharmonics have much smaller synchronizing ranges than odd subharmonics; Fig. 16 shows synchronizing ranges of second subharmonic sustained oscillations for $C=100$ μf and for several values of the supply voltage E. Synchronizing ranges of even subharmonics are highly increased by polarizing the core.

Mechanism of Starting Sustained Oscillations

To study the mechanism of generating sustained oscillations (the third subharmonic being considered), the output voltage across the condenser was applied to the X-plate of a cathode-ray oscillograph. A third steady-state subharmonic oscillation obtained by a separate circuit is applied to the Y-plate. Both oscillations on X- and Y-plates are partially filtered with half-section low-pass filters. The Lissajous figure in Fig. 17(C) shows clearly that the oscillation starts and builds up in a synchronized state. The waveforms as well as the Lissajous figure at the steady state are also shown in the same figure. During building-up, energy, being obtained from the supply, must be injected to the oscillation at the right instant and in the right direction. Therefore the oscillation must build up in the synchronized state and remain synchronized in the steady state. However, if starting is aided by an initial high charge on the condenser, the oscillation starts freely and damps until the conditions favor synchronization, and the oscillation is pulled in and continues synchronized until the stationary state is reached; see oscillogram of Fig. 18.

Oscillations Just Outside the Locking Range: Pulled Oscillations

As stated before, these pulled oscillations are actually subharmonic oscillations but modulated mainly in phase. Since the apparent beat frequency is very low; recording on a moving film is a convenient method for studying these oscillations, see oscillogram of Fig. 13. A 50-cycle timing wave was recorded on the same oscillogram for comparison. The apparent beat frequency was very low so that the oscillations in Fig. 13 appear as if they were nonperiodic.

Appendix

$$D_1=\frac{1}{2}\,\omega\phi_3\phi_1^3\left[\frac{3}{4}\,a_3+\frac{15}{16}a_5(2\phi_3^2+\phi_1^2)\right]$$

An Electroluminescent Digital Indicator With Elpak Translation Logic

E. A. SACK
ASSOCIATE MEMBER AIEE

Synopsis: In many instances our advancing technology today demands that information be presented to the human observer in digital rather than analog form. A very desirable digital indicator can be achieved if a set of mutually insulated back electrodes or segments are formed on an electroluminescent panel. By applying excitation to selected combinations of these segments, bright numerals or other figures may be formed. The logic required to translate from the input information to the segment code can be accomplished with a number of conventional devices. However, a relatively new switch, known as an Elpak relay, has proved to be well suited to this application.

THE PHENOMENON of electroluminescence is finding a wide range of device application quite apart from its obvious potential as a general source of illumination. This paper will describe an electroluminescent device, known as a digital indicator, which provides a very desirable means for visual presentation of numerical information in digital form. Another electroluminescent device, the electroluminescent-photoconductive relay, or Elpak, has been used to effect the necessary translation for properly exciting the digital indicator. This will also be described.

In recent years, there has been a strong trend toward the presentation of information to the human observer in digital rather than analog form, i.e., the output member of the modern system displays the information as a number or symbol rather than as the displacement of a pointer. The significance of this trend is evidenced by the availability of a growing selection of digital instruments such as digital voltmeters and counters.

A number of disadvantages may be cited for the conventional analog meter. Not the least of these is the fact that many systems, particularly those which utilize digital computation, far surpass the accuracy capabilities of the conventional analog indicator. For example, it would be ridiculous to throttle the potential accuracy of a 6-place counter with an analog output member such as a 1% D'Arsonval meter. Moreover, in a conventional analog instrument only a small portion of the meter face is active in informing the observer of the desired data. For example, assume that the needle on a 4-inch-square panel meter is pointing to the figure 2. In recognizing this reading, the observer is concerned with an area of, perhaps, 1/8 by 1/2 inch on the meter face or about 0.4% of the panel area occupied by the instrument. In a day and age when panel and switchboard space is at a premium, this is very poor utilization of space. Finally, the presence of a multitude of figures and lines on a conventional meter face is confusing to the observer and results in hesitation in reading, interpretation errors, and observer fatigue. The multimeter, with its confusing array of scales and markings is a prime example of how serious this problem can be.

The digital indicator is a distinct step toward overcoming these disadvantages; the accuracy of such a device can be equal to or surpass that required by the system. The digital display to be described occupies no more panel space than is required to "write" down the numeral, and size, and hence the viewing distance; and is completely flexible. Reading errors and fatigue are greatly reduced with the digital presentation because there is no need for the observer to worry about scale factors or to interpolate between scale marks.

Several different types of digital indicators are available. One model utilizes a plurality of individually excited neon lamps spaced behind a mask with numerical cutouts. Another uses painted tabs which are moved, mechanically, into the viewing window. A more modern approach is represented by a device which is essentially a multielectrode neon lamp in which the active electrodes are in the shape of numerals. Another relatively new unit is, in effect, a tiny theater in which the numerals are projected onto a ground glass from the rear by a set of incandescent lamps. Undoubtedly, still others are familiar to the reader. Each

Fig. 1. Westinghouse electroluminescent panel

possesses certain advantages and disadvantages. It is believed that the device to be described is potentially superior to these earlier approaches in a number of important respects.

Electroluminescent Digital Display

Fig. 1 shows a Westinghouse electroluminescent panel. A transparent conducting layer is provided on the back of a glass base plate as the first or front electrode. Next, a plastic-phosphor dielectric is sprayed on the panel. Finally, an aluminum film is evaporated on the dielectric to form a second or back electrode. In effect, the structure is a parallel plate capacitor with a composite phosphor-plastic dielectric.

When a time-varying electric potential is applied to the electrodes, the alternating gradient in the phosphor causes it to luminesce. The theory and technology of intrinsic electroluminescence have been extensively reviewed in the literature and need not be repeated here.[1] Let it suffice to summarize the pertinent terminal characteristics of such a "lamp" as follows:

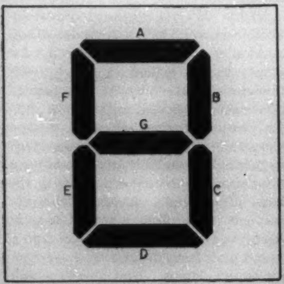

Fig. 2. Digital indicator segment pattern

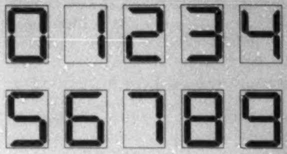

Fig. 3. Numerals formed using the 7-segment pattern

1. The brightness of an electroluminescent cell generally increases with applied voltage and frequency.
2. The color of the light depends upon phosphor composition and frequency.
3. Electrically, an electroluminescent cell looks like a slightly nonlinear capacitor with a power factor on the order of 10% to 20%.
4. Build-up time to full light output is no more than several cycles of the applied power.

The aluminum back electrode need not be a continuous sheet. Instead, the aluminum may be evaporated through a mask to form any desired pattern of insulated electrodes on the back of the panel. When power is applied to any one of these electrodes or segments, only the phosphor under that electrode will luminesce. As a matter of fact, since typically the phosphor-plastic dielectric is only a fraction of a mil thick, the effects of fringing about the electrode are almost entirely negligible.

Contact may be made to the aluminum segments in a variety of ways. For temporary experimental setups, conducting rubber is ideal, since the connection may be established repeatedly without damage to the aluminum film. For finished devices a variety of printed-circuit contact techniques may be utilized.

If the back electrodes are evaporated in a pattern similar to that shown in Fig. 2, any numeral from 0 to 9 may be formed by applying excitation as indicated in Fig. 3 and Table I. Naturally, the transparent conducting electrode is common. Fig. 4 shows a 2-digit indicator in operation.

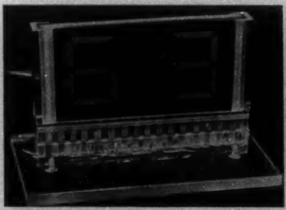

Fig. 4. A 2-digit indicator in operation

WESTINGHOUSE

Fig. 5. A 3-digit indicator in a counter

It is interesting to note that various observers report individual preferences in how the seven segments should be shaped to give the most pleasing display. This is not surprising in view of the fact that humans vary widely in the way they shape numerals when writing them. Some like a slanted form while others prefer the vertical shape. However, all observers agree that no difficulty is experienced in recognizing the numbers formed using the 7-segment code.

The shape and size of the numerals on the electroluminescent plate is, of course, completely flexible. More than one number may be put on a single plate, or single numeral plates may be arranged side by side to achieve any number of digits. Other segments may be included to provide polarity marks, decimal points, commas, arrows, vector marks, etc.

Fig. 6. Construction of the 3-digit indicator

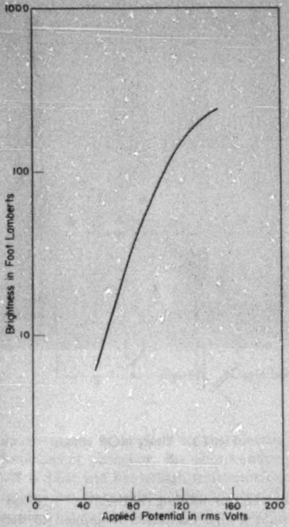

Fig. 7. Brightness of low-voltage electroluminescent panel as a function of applied voltage

Table I. Segment Excitation Program to Form Digits 0 Through 9

	Digit Formed									
Segment	0	1	2	3	4	5	6	7	8	9
A	X*		X	X		X	X	X	X	X
B	X	X	X	X	X			X	X	X
C	X	X		X	X	X	X	X	X	X
D	X		X	X		X	X		X	X
E	X		X				X		X	
F	X				X	X	X		X	X
G			X	X	X	X	X		X	X

* X denotes excitation applied.

An electroluminescent digital indicator for a 3-digit counter is shown in Fig. 5. The construction of this panel is shown in Fig. 6. The electrode segments for the three digits are first evaporated on the electroluminescent plate. A printed-circuit board is prepared with conductors to carry power to the segments through a set of holes drilled to coincide with the segments. The printed-circuit board and electroluminescent panel are then glued together and conducting cement is poured in the holes to establish contact between the printed conductors and the segments. The finished panel may be plugged into a standard printed-circuit base as shown.

There are other fabrication techniques which have been used successfully. By the use of the proper plastic interlayer, the printed circuit may be put right on the electroluminescent panel. The inert plastic layer prevents excitation of the phosphor under the conductors.

Power Requirements

The voltage and frequency needed to power the electroluminescent indicator depend on the brightness desired and the cell construction. Brightness requirements, of course, depend on the ambient lighting conditions. In a low light environment as little as 10 to 30 foot-lamberts might be completely adequate. This is comparable to the highlight brightness at which people tend to operate their television sets for living-room viewing conditions. In surroundings with moderate light levels, such as laboratories, control rooms, etc., 50 to 80 foot-lamberts may be required, while in a high-ambient location, e.g., in direct sunlight, several hundred foot-lamberts may be barely adequate.

Under high-intensity excitation conditions, brightnesses of 2,000 or more foot-lamberts have been attained with plastic-embedded electroluminescent panels.[2] Recent improvements in phosphors and cell construction make it possible to achieve excellent light output with relatively low-voltage excitation. Fig. 7 shows the brightness of a low-voltage Westinghouse electroluminescent panel at a frequency of 10 kc. It may be seen that sufficient brightness for most applications is available with less than 150 volts rms applied to the cell.

At 100 volts, 10 kc, the power dissipated in this type of electroluminescent panel is approximately 50 milliwatts/cm^2 (per square centimeter). For the indicator shown in Fig. 5, the maximum power for each numeral is only 66 milliwatts under typical operating conditions. The capacitance of the low-voltage panel is

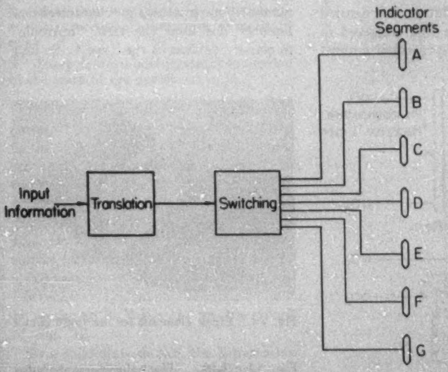

Fig. 8. Translation and switching for electroluminescent indicator

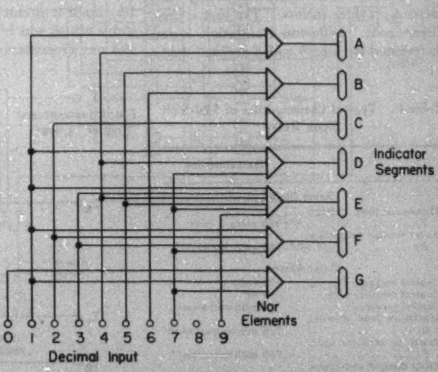

Fig. 9. NOR element translation circuit for the indicator

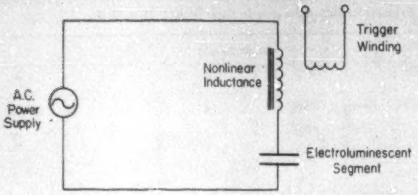

Fig. 10 (left). Ferroresonant switching circuit for the indicator

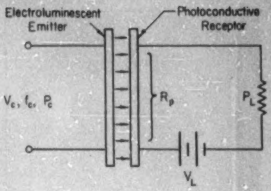
Fig. 12 (right). Elpak relay: load circuit



approximately 280 micromicrofarads/cm^2 so that the capacitance of each segment, in the display of Fig. 5, is less than 140 micromicrofarads. Under these circumstances the excitation for ten digits or more may be supplied by a small transistor converter.

Switching and Translation

A 2-part process is involved in selecting the proper combinations of segments to form the numeral indicated by the input signal. As shown in Fig. 8, the input information, be it in binary-coded decimal or decimal form must be translated into the 7-segment code. Power must then be switched to the proper segments in accordance with the code signals.

Starting with no power applied to the screen, and switching to turn elements ON, 49 closures are required to form the ten digits. On the other hand, starting with all segments ON and switching proper combinations OFF, only 21 switching operations are involved. The latter case is obviously the more desirable, i.e., it is more efficient to use switching logic which removes, rather than applies excitation to, the segments in order to form the desired digits.

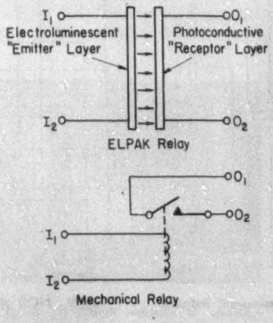
The form of the translation circuit will depend on three factors. The first is the input code. Different translation logic is required for binary-coded-decimal than straight-decimal input. The translation circuitry will also depend on the logic elements to be used. Finally, the form of the logic circuitry will vary with the components used to apply and remove excitation from the segments.

Table II. Typical Characteristics of 120-Volt Elpak Relay

	Characteristics
Relay Open	
Maximum load voltage, V_L	120 volts
Relay contact resistance, R_P	300 megohm-cm^2
Relay Closed	
Control voltage, V_C	120 volts
Control frequency, f_c	5 kc
Control power, P_C	24 milliwatts/cm^2
Maximum load current, i_L	7.5 milliamperes/cm^2
Power to resistive load, P_L	750 milliwatts/cm^2
Relay contact resistance, R_p	2,680 ohm-cm^2

Fig. 9 shows a NOR element translation circuit which may be used when a signal received on one of ten busses (decimal code) is to be displayed as a corresponding digit using the 7-segment code. The NOR element is a component which provides an output only so long as no signal is received on any of its input leads. When a signal appears on one or more of the leads, the output disappears.

Quite often the components available for the logic circuitry, such as small transistors or diodes, cannot handle the voltages which must be applied to and removed from the segments. Then it is necessary to provide output devices which, when driven by the logic signals, will perform the switching operation. Among the elements which may be used for this purpose are vacuum tubes, transistors with step-up transformers, saturable cores and semiconductor devices which exhibit thyratron characteristics. A very satisfactory approach is to make the electroluminescent segment part of a ferroresonant circuit, as shown in Fig. 10. Such a circuit exhibits two distinct stable states which may be triggered in and out of existence by a small current in a trigger winding on the core.[3] In one state a high excitation is applied to the segment, while in the other the segment is dark.



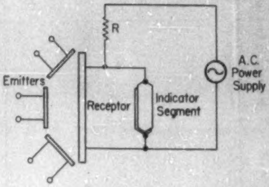


Fig. 13. Elpak NOR circuit

The next section describes still another switching device which is capable of performing both the translation and the switching functions. In many ways this element is ideally suited to perform these operations for the electroluminescent indicator.

Elpak Logic

If an electroluminescent cell and a photoconductor are associated as shown in Fig. 11, there results a switching device, here called an Elpak relay, which has a number of interesting characteristics. Loebner has used the term "optronic" to classify devices of this type.[4] So long

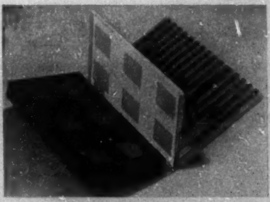

Fig. 14. Elpak elements for the logic circuit

Fig. 11 (left). Electroluminescent-photoconductive Elpak relay

Fig. 15. "Logic box" for the Elpak plates

as no power is applied to the electroluminescent phosphor, the photoconductor is dark and has a high resistance between its terminals. When power is applied to the electroluminescent "emitter," however, the illuminated photoconductive "receptor" assumes a resistance which may be five orders of magnitude below its dark state.

In many ways the Elpak relay is closely analogous to the mechanical (magnetic) relay, certainly far more so than either the vacuum tube or the transistor:

1. There is excellent electrical isolation between the control and load terminals.
2. The load terminals are bilateral. (No bias is needed to switch dual polarity current.)
3. More than one receptor may be arranged to view a single emitter, thus simulating a multipole relay.
4. More than one emitter may illuminate a single receptor to simulate a multicoil relay.
5. There is an inherent visual indication of the state of the device.

The control power and allowable load power of an Elpak relay are proportional to the active area of the electroluminescent and photoconductive surfaces. In the case where the two layers are congruent and directly adjacent, the terminal characteristics may be specified for a unit area of the relay. For a 120-volt zinc sulfide electroluminescent emitter facing a 120-volt photoconductive cadmium sulfide receptor, typical characteristics might be as shown in Table II; see the circuit of Fig. 12.

As a solid-state device, the Elpak relay has advantages of life, reliability, and ruggedness over the mechanical relay. At present, however, it has a disadvantage which limits its application. Sensitive photoconductors, such as cadmium sulfide, are slow to respond to variations in illumination. Depending upon the light levels available, from 0.1 to 1 second may be required for the photoconductor to change from one extreme of conductivity to the other.

The translation circuit for an electroluminescent digital indicator has been built with the use of the Elpak relay. This seemed to be appropriate for a number of reasons. First, the idea of using electroluminescent logic with the electroluminescent indicator was quite intriguing. Second, the power-handling capabilities of available photoconductors are such as to obviate the need for a separate control stage following the logic. Third, impedance levels and excitation requirements of the indicator segments and Elpak relays are excellently matched and, finally, the speed of response of the photoconductor appeared to be adequate for this application.

The Elpak logic circuit which was constructed used Elpak NOR elements to translate from decimal to the 7-segment code with the arrangement shown in Fig. 9. An Elpak NOR circuit is shown in Fig. 13. So long as no power is applied to any of the electroluminescent emitters, excitation is applied to the display segment. When a signal is received on one or more

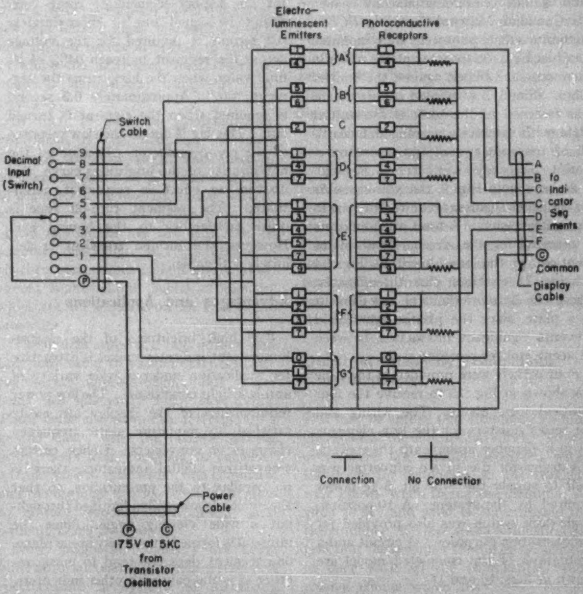

Fig. 16. Circuit of electroluminescent translation device

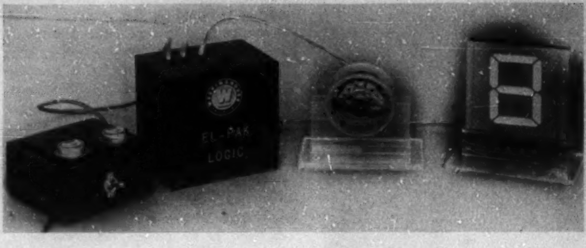

Fig. 17. Demonstration indicator with Elpak translation logic

of the emitters, the photoconductive receptor removes the output excitation.

In the model which was constructed, it was convenient for geometrical reasons to use a separate photocell for each emitter and then connect all of the photocells for a particular NOR element in parallel. This resulted in a receptor with a power-handling capacity which was many times that actually required.

The electroluminescent NOR elements were fabricated in plate form as shown in Fig. 14. Six emitter electrodes were evaporated on the back of a 2- by 4-inch zinc sulfide electroluminescent panel. Six Canadian Marconi Company *PC1-04* cadmium sulfide photocells were mounted in a black plastic receptor plate, which in turn was sandwiched against the emitter plate. Finally, a printed-circuit board was fastened to the back of the emitter plate with conductors arranged to carry all of the emitter and receptor connections to a special socket in the "logic box."

As seen from Fig. 9, the NOR elements for the seven segments require from one to six emitters each. A total of 21 emitters is required for the screen. Four plates identical to the one shown in Fig. 14 provide 21 emitters plus three spares. There can be more than one NOR element in a plate, since the plastic light shield prevents significant interaction between adjacent emitter-receptor pairs.

Four sockets were provided in the logic box shown in Fig. 15 to receive the four identical logic plates. The wiring and the series resistors for the NOR elements are in a chamber underneath the sockets.

A transistor d-c to a-c converter was built to supply the 175-volt 5-kc power required by the system. A 10-position, single-deck switch was also provided for demonstration purposes. A circuit and a photograph of the completed model are shown in Figs. 16 and 17.

The performance of one Elpak NOR element and associated display segment is, of course, typical of all of them. Tests show that so long as the emitter is off, 165 volts of the 175 volts applied appear across the segment. Under these circumstances, the brightness of the segment is on the order of 80-foot-lamberts. When power is applied to the emitter, the potential across the display segment drops to about 16 volts. With this excitation, the segment is "out" (less than 0.01 foot-lambert).

With the Elpak relay, it takes longer for the display segment to come "on" than to be turned "out." Approximately 0.2 second is required for the voltage across the segment to reach 64% of its final value when the logic turns the segment "on." Approximately 0.3 second is required when the element is turned out. This lag is due to the slow response of the photoconductor. Because of the nonlinearity of the brightness curve, this uneven lag effect is somewhat accentuated. The segment turn-off time is quite satisfactory to the human eye. However, the turn-on transient is definitely noticeable.

Advantages and Applications

The high brightness of the electroluminescent indicator makes it attractive for application under a wide variety of ambient-light conditions. The low power requirements of the display are easily satisfied by miniature static frequency changers or converters. Unlike certain competitive digital indicators, there is no parallax to the presentation, so that the numerals are easily identified throughout a wide viewing angle. Since the numeral is formed completely in one plane, one segment does not tend to mask another as is the case with other indicators. The possibility of varying the color of the electroluminescent numeral adds another degree of freedom to the display.

The size of an electroluminescent panel is limited only by manufacturing convenience. One-foot-square cells are already available. Numerals over one foot high may be made by using more than one panel, since there need be no dead area around the edges of the cell.

On the other end of the scale, numerals may be made whose height is no more than a fraction of an inch. As noted earlier, a display on an electroluminescent panel may have very fine resolution.

The potential utilizations of an indicator of this type are too numerous to list in entirety. There are applications in automation, process supervision, testing and quality control, computer readout, annunciation, and score display. Since the form of the numeral and auxiliary markings is easily varied, the electroluminescent indicator may be tailored to match the application.

The techniques described in the foregoing may be carried over into precoded graphic displays for power system switching, pipe-line-flow monitoring, and industrial process supervision. Here, in particular, the outstanding color flexibility of electroluminescent lighting will be a great asset.

Conclusions

The electroluminescent digital indicator provides a numeral display with low parallax, high brightness, excellent readability, low power requirements, variable color, and wide dimensional flexibility. The logic and control which are required to translate information from a particular code to the 7-segment code may make use of a wide selection of conventional devices. The Elpak relay provides a desirable means for accomplishing both the translation and the control in a single step. The Elpak logic circuit which was built to translate from the decimal to the indicator code has proved to be very satisfactory.

Introducing Young Engineers to the Appreciation of Magnetic Amplifier Problems

L. A. FINZI
MEMBER AIEE

YOUNG ENGINEERS entering a field of electrical development and design probably are equipped with some initial knowledge of that area, but may lack a balanced perspective of the relative significance of phenomena and facts and methods. In fact, they may have altogether immature notions of the ways by which engineering problems are solved. This is particularly true if their college training has been of a dreary "learning-by-the-book" variety, where procedures and "formulas" may have been derived or accepted without adequate effort to appreciate their physical significance, limitations and implications, and where so-called problems really may not have extended beyond disguised pretexts for algebraic or arithmetical manipulations within the rigid frame of those formulas.

In many fields the young apprentice is assisted by dependable elements of experience gathered by others and expressed, for instance, by company files and collections of test results on earlier products, and by the advice offered by senior colleagues on the job. This body of knowledge should not be considered as unassailable and final, but certainly it is useful in bringing the problems at hand within the grasp of the beginner. The situation is more difficult in newer fields, and in particular in the rapidly moving field of nonlinear ferromagnetic devices, with which this paper is concerned.

Magnetic amplifiers are deceptively simple devices in their structures and in their essential circuitries; it is not difficult to acquire some notion of their general operation in a qualitative way, and the design of the components is initiated with rather elementary considerations that are not different from those of small transformer design. But a few steps beyond this initial stage the real difficulties appear.

The ways of thinking and the techniques introduced in the analysis of different systems seem dubious to the beginner, and vary inconsistently from case to case; the most important material properties appear elusive to an extent unsuspected at first. Though the technical literature is now emerging from the confused state of earlier years and good treatises are becoming available, the unconventional character of this nonlinear field is conducive to misinterpretations, and the immature reader may not be immediately able to make good use of these sources. Moreover, in proceeding to a reduction to practice in a design with quantitative specifications of performance or in a semiquantitative development of new and untried ideas, many effects of a most unclear nature are likely to appear, for which the individual must resort to empirical approaches, using his own ingenuity.

In fact, it may be admitted that empiricism is the mainstay of most magnetic amplifier work, and there is nothing disgraceful in this admission since all branches of engineering and all natural sciences have evolved in this way; empirical approaches are not antithetic to scientific reasoning. But a fruitful empiricism presupposes insight and critical, almost sophisticated, habits of thought which are not acquired on the spur of the moment.

These difficulties are not unique and they may occur to various extents in any engineering apprenticeship, but newer fields are inherently more mystifying. These fields also seem characterized by a greater haste, with the restless shifting of engineers from company to company or from task to task within one company, and the beginner is often required to grow to mature responsibilities quickly and without much assistance.

Now, magnetic amplifiers are being built quite successfully, meeting stringent specifications in systems of increasing complexity with a wealth of clever new ideas and disclosures concerning the use of the basic components, and all this is done to a large extent by young engineers not far from their college years and equipped perhaps with no more than some tables of core and wire sizes. This proves that many college graduates are endowed with intelligence, ingenuity, and remarkable endurance. On the other hand, the ordinary process of amplifier development and design usually demands a great effort, is costly, and involves a great many engineering man-hours.

Here the question arises whether effective forms of training may be devised for the swift growth of competent designers. The aims are to economize on some part of the time that the young engineers must spend searching their own ways and learning from their own mistakes, and further to rescue individuals who in the process may coast into spiritless technical activities of an indiscriminate hit-and-miss variety.

A schooling of this sort should not be conceived as a teaching of special technologies for special tasks. Factual information and manuals of design, etc., are most useful in competent hands but they do not in themselves point the way to attaining competence. The latter relies on the acquisition of keen mental habits in the detection and interpretation of the amplifier phenomena; in the considerate choice of meaningful methods, analytical and experimental; and in the selection of whatever simplifying assumption may seem expedient for quick and significant answers.

It remains to be seen whether anything can be done practically and in a short time to achieve some of these lofty aims. The considerations that follow express some tentative ideas on this matter. Apologies are made for the belaboring of some issues that may seem self-evident to many readers, but the educational process is made difficult in this field by the extreme ease with which misconceptions arise in the beginner's mind.

Quest for Simplicity; Simplifying Assumptions

It may be agreed that simplicity should characterize the educational effort. However, there are pitfalls associated with the desire for simplicity, as any teacher well knows when facing the dilemma of what to say and what to leave unsaid to the student. No one would seriously suggest that the beginner should be presented at once with all the complexities and elusive effects which may well emerge significantly in his future work. But neither is a starting point obtained in

Y., February 2-7, 1958. Manuscript submitted October 14, 1957; made available for printing November 13, 1957.

L. A. Finzi is with the Carnegie Institute of Technology, Pittsburgh, Pa.

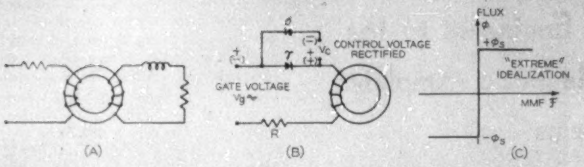

Fig. 1. A—A simple reference circuit. B—A voltage-controlled half-wave amplifier. C—The extreme idealization of core properties

explanations which explain hardly anything constructively.

For instance, the idea that the magnetic amplifier is "sort of a reactance" is misleading and also finds little use in any further description of amplifier circuits. The action of the amplifier in the load circuit is by no means that of inductance; also a coil wound on a core of a square-loop material really does not possess any one of the properties inherent to the concept of inductance. The terms "saturable reactor" or "variable impedance" are used in the slang of the art, but this is not a reason for building on such usages.

The beginner, who by definition knows no better, is bound to be literal-minded and should not be exposed needlessly to malapropisms and far-fetched analogies. One is aware of the usefulness of certain linearizations of core properties in certain aspects of certain problems, but this is not a matter for generalizations out of context. The beginner's background in magnetic circuits may be already anchored on sophomoric treatment of the subject in college in which there was unwillingness to depart from linear or linearized procedures (with hysteresis loops injected, none too clearly, as a matter of curiosity). Therefore need may be felt early in the beginner's training to shock him into the ways of square-loop thinking which are more pertinent in many problems of modern magnetic-amplifier applications.

Forms of simplicity that are educationally questionable are also forms in which a comparatively complicated system is made simple by the precipitate introduction of extreme idealizations. The series-connected saturable reactor with resistive loads and zero control-circuit resistance, and with ideal cores of infinite and zero permeabilities, is an example of these approaches. Such treatments quite skillfully describe certain interesting patterns of behavior, and their place in the art should not be belittled. But strong reservations are voiced here in principle against the postulation of assumptions and against the immediate use of reasonings by limiting cases in the educational approach without careful and reasoned justification.

The beginner is not in the position to appreciate what the assumptions basically stand for and can only accept passively the methods. Soon enough, however, he may recognize that his interests as a designer are in, for instance, the behavior of saturable reactors at low signal levels or in their operation as even-harmonic modulators, where the assumption of unimpeded flow of harmonics is self-defeating; or in extension to doublers and center-taps whose finite gains cannot forever be complacently attributed to leaky rectifiers, and so on. A search for better procedures may be difficult at this point if exceedingly simplified ways of thinking have been already ingrained in the mind of the uncritical beginner. Probably, because he has been exposed to a vague treatment of unspecified magnetizing currents, interactions, and harmonics, he may infer, with frustration, that the "theories" have little bearing on his practical problems; he may find it difficult to reach meaningful conclusions by himself, and plunge into brute-force attempts to meet his immediate assignments.

Moreover, exceedingly simplified treatments tailored to fit a particular device do not lead to the coherent understanding of the many other systems or devices grouped under the comprehensive heading of "magnetic amplifiers," and the experience that one may have gathered in the earlier study of a certain system remains unrelated to newer tasks. This is a strange result, since in all cases the same basic components are found utilized with essentially similar mechanisms of operation.

The approach suggested in the following is one in which simplicity is sought in a different manner. A physical system is considered first which is comparatively simple in itself, i.e., a core with some windings. A fascinating wealth of meaningful problems may be found even at this level in applications of practical interest, while a later transition to more complex multicore system may coherently evolve.

No simplifying assumptions are postulated a priori for this; rather the properties of actual components (cores, rectifiers, etc.) are considered, as known from the recent technical literature and manufacturers' data and as recognized by experimentation, and the essential meanings of the fundamental laws expressed in the system equations are examined. It is only at this point that a search for idealizations and simplifications may be initiated profitably for any specific problem at hand.

In any problem of engineering for which no pat solution is known in advance (in which case, it would not actually be a problem), the choice of approximate simplifying assumptions is, more or less, a matter of calculated risks. Whenever one is required to replace an actual situation with an idealized (and thus different) one, the possibility of later "agonizing reappraisals" is implicit. This point may not have been stressed in college and this may be one reason for the hasty statements of disillusioned engineers to the effect that theories are of no use in the solution of their practical problems. Magnetic-amplifier problems require a most inquisitive attitude in these choices. Students should be encouraged by all means to use their ingenuity to devise and try simplified approaches, extreme as these may be, but some discrimination must be fostered throughout the process.

Organization of Course Content

General Features; Voltage Reset

The implications of Kirchhoff's voltage law as applied to one toroidal winding with resistances or other components in series may be reviewed first. It is suggested that the habit is formed of writing down the circuit equations carefully, simply because this is the most convenient and compact way to express the physical laws. Even when it is found that the solution of these equations may be cumbersome or impossible, their judicious consideration and reconsideration at all steps constitutes valuable guidance in partial predictions, in the interpretation of empirical findings, and in extrapolations by similitude.

Concepts of flux and flux linkages may be reviewed to emphasize the volt-time integral idea and to point out the principle of nonrectification for circuits supplied from periodic voltage sources of zero cyclic average. Stray fluxes and partial flux linkages and winding capacities may be mentioned without loss of simplicity because these concepts are within the student's grasp. No particular restrictions are needed, so far, concerning the core properties. In view of the highly nonlinear problems to be tackled later, inductance concepts L and M may well be omitted. Essentially, inductances are not fundamental physical quantities, but rather man-made definitions, introduced as an abbreviation of a sort, convenient but not indispensable even in the treatment of linear circuits.

Square-loop cores are considered next, and systems with cores of "gradually varying differential permeability" are postponed to a later time as distracting in the introduction of novel concepts of more immediate interest. The properties of square-loop cores are expressed well enough at this point by the major loops, static and dynamic for sinusoidal fluxes, and by dynamic minor loops exhibited in catalogs of core manufacturers. Some of these loops as well as the peculiar wave forms of magnetizing currents may be displayed on an oscilloscope with elementary techniques. (Direct experimentation should be an integral part of the training in this field in which the oscilloscope remains the primary tool.)

A comparison with similar loops of other materials (e.g., hot-rolled steel) reveals three peculiar features of square-loop materials:

1. Sharply defined saturation flux densities: $\pm B_s$.
2. Tendency of the core flux to remain at a set value upon removal of the magnetomotive force.
3. Comparatively small field intensities in flux excursions over the unsaturated range.

Feature 1 leads to the definition of the core volt-time area and of the normal excitation. A simple application is found, for instance, in the reference circuit of Milnes,[1] in its basic form; the influence of changes of line voltage and frequency may be investigated and the usefulness of the secondary network may be recognized; see Fig. 1(A). The inverter of Royer[2] may be considered next; the less than perfect "squareness of the top of the loop" is a useful factor in the operation of this inverter, while, on the other hand, this effect may well be ignored in many other instances.

Feature 2 is utilized most evidently in Pittman's time-delay device[3] and in many other transistorized devices. The thyratronlike action of a half-wave amplifier with resistive load may be investigated next in terms of the preset flux level ϕ_p. The well-known voltage-reset half-wave circuit of Fig. 1(B) may be used to show one particular way in which ϕ_p can be made dependent on a signal v_c. Hence transfer characteristics and gain concepts are presented, with careful and specific definitions to avoid ambiguities that are not unusual.

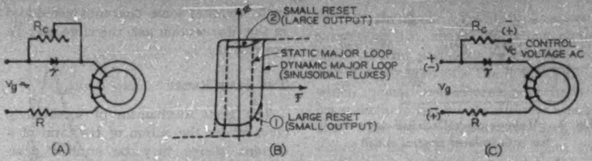

Fig. 2. A—A resistance-controlled half-wave amplifier. B—Utilizing the information of core catalogs. C—An instance of control by nonrectified alternating voltages

Cases of sinusoidal gate voltages and rectified sinusoidal signals are followed by conditions of more general waveforms of signal and gate voltages, larger or smaller than normal. Some fundamental formulas of design, for the core and the gate winding, may be presented at this stage, which are common to most magnetic amplifiers and some comments may be given on wire tables, winding factors, and shuttle limitations.

Other types of loads, resistive-inductive, with or without discharging rectifiers, with d-c back electromotive forces, etc., may be considered next, with the recognition that the concept of firing leads to load-circuit analyses similar to those of thyratron situations, while the time of extinction of gate-winding currents affects the control, as it determines the time at which reset can be initiated by the signal. The coincidence counters, the ring counters, the digital components of Ramey,[4] and the multiplier of Mathias, et al.,[5] may be examined also.

Feature 3 has been used in all previous instances only to note that certain resistive voltage drops may be neglected in the voltage equation. (Some numerical examples of the relative order of magnitude of the various terms of the voltage equation should be given.) That is, the extreme 3-zone idealization of Fig. 1(C) relating core flux ϕ to core mmf (magnetomotive force) is accepted for preliminary purposes, though this matter may deserve reconsideration, depending on the accuracy required in the various cases.

The resistance-controlled half-wave circuit of Fig. 2(A) may be considered next, as a further instance in which the voltage equations still describe the operation. But here the controlling agent is the voltage drop of resetting currents through the resistor R_c; hence some notice must be taken of these currents. The information concerning core mmf must be reexamined, and on this occasion some additional comment is in order concerning dynamic widenings of the major loops for sinusoidal fluxes at the various frequencies. The student familiar with eddy currents will accept the idea that larger mmf may be needed at higher values of rate of change of fluxes, perhaps to compensate for the reaction of induced eddy currents, although the shapes and widenings of the dynamic loops of the catalog may indicate to him that more is involved than the eddy currents of his sophomoric experience.

A prediction of the transfer characteristic, output versus R_c, is possible, if it is noted that large resets, minor loop 1 in Fig. 2(B), are characterized by rather large values of $d\phi/dt$, in dynamic processes which are similar to those of sinusoidal voltage of rated frequency, with comparatively large resetting currents throughout, while small resets (minor loop 2) are associated with small resetting currents; for intermediate outputs the reset currents have somewhat intermediate values. This is rough reasoning which, however, is not without practical value; the essential phenomena have been expressed crudely but have not been ignored. The student will understand how core-testing procedures could be sought if more accurate predictions were important to him and how certain idealizations of core properties (e.g., the rectangular remanator concept or the empirical equation $\mathcal{F} = \pm\mathcal{F}_c + K\,d\phi/dt$) could be used to expedite his work. A similar approach is required in the example of Fig. 2(C).

The 2-winding amplifier circuit of Fig. 3 is essentially a pretext to review transformer concepts. The beginner, under the cursory college treatment of short-circuit and no-load tests, vector diagrams, etc., pertinent to power transformer techniques, may have missed transformer concepts of more basic interest. Hence there may be need to write the differential equations associated with the various windings, introducing mmf with clear sign conventions and dot notations. The point should be made that the instantaneous terminal quantities describing the core operation are its flux ϕ, the flux rate (or voltage per turn) $d\phi/dt$, and the mmf $\mathcal{F} = \Sigma Ni$ resultant from the instantaneous

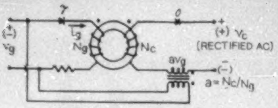

Fig. 3. Voltage-controlled half-wave amplifier with isolated control circuit

currents in all windings; techniques of reductions of secondary quantities to primary in terms of turns ratios $a = N_1/N_2$ and ratios squared, etc., result then directly.

The N^2/R concept for the two windings should be emphasized, associating it with their copper volumes; hence another concept of design is introduced which is most important in questions of optimum design of all amplifiers. (No harm is done if formulas for self-inductances and mutual inductances and Q's are recalled at this point in design.)

This is also the time, dispelling any confusion, to point out that voltage gains arising from ratios of transformation are different from the gains inherent in amplification.

The peculiar features of a saturable-core transformer are displayed in the system of Fig. 4, which provides short high-energy pulses for stitch-welding purposes upon periodical reversal of the d-c line voltage. A tentative design of the system components may be attempted, for given pulse specifications, under the assumption of negligible secondary inductance and with some idealization of the weld resistance. The simultaneous use of the concepts of volt-time integrals and of current-time integrals is interesting. As a separate problem, the oscillatory discharge may be investigated that takes place if the secondary inductance is large (assuming, for simplicity, that the switch is opened as soon as the core reaches saturation).

Multicore combinations of the basic voltage-reset half-wave circuit may be studied next. Fallacies of indiscriminate "building-block" ideas may be detected by examining the poor operation of a-c-output 2-core systems obtained by connecting two of the blocks back-to-back; here the coupling through the load branch makes it difficult or even impossible to obtain a reasonable operation; i.e., the transfer characteristics are not comparable to those of the basic half-wave circuit. In this connection, Maine's papers on single-phase and polyphase combination of half-wave components[6] are worth-while reading. (The 2-core half-wave reversible-output amplifier of Lufcy[7] and others similar to this may also be examined, although a more appropriate treatment really requires some concepts introduced in the next section and therefore may be postponed.)

THE MMF RESET

The reset mechanism of square-loop cores under the action of the mmf of a current source may be studied next. This mechanism appears in the control of various types of magnetic amplifiers and in the switching of memory cores and transfluxors. Oscillographic tests of reset core-voltage versus time are performed easily (Fig. 4) conveying more specific ideas of dynamic behavior (i.e., the three terminal quantities $\mathfrak{F}$, ϕ, and $d\phi/dt$ are interrelated, at least for the particular process of flux reversal from pronounced saturation). Industrial methods of core testing and matching may be described.

Use of oscillographic tests of core reset voltages has been made by Critchlow, et al.,[8] to predict transfer characteristics of half-wave and 2-core self-saturating amplifiers controlled by constant-current sources. The processes may be examined that take place in gate-limited intervals (i.e., in those intervals of the reverse half-cycle during which the self-saturating rectifier becomes conducting and the core reset is limited by the gate voltage) and in constant-mmf intervals (in which the rectifier blocks). The rather low limiter voltages recognized in the doubler after firing, once more warn against unwarranted building-block notions, and the influence of gate-winding resistances is seen.

The mechanism of operation of these self-saturating circuits over the negative branch of their transfer characteristic is also easily described. This leads to consideration of the operation around minimum output and to the introduction of reasonable speculations concerning those triggering phenomena which are particularly evident at gate voltages lower than normal. As these phenomena are associated with flux swings initiating from less than pronounced saturation, the expedient of auxiliary pulses of bias mmf suggested by Morgan,[9] becomes understandable; also some reasons are seen why rounded-top materials (such as 48-alloy) are less critical in terms of triggering.

The biased-rectifier-amplifier (BRA) of Morgan[10] may now be examined in some of its simplest configurations to emphasize the importance of gate-limiter voltages and in discussing more closely the behavior of rectifiers and their threshold voltages.

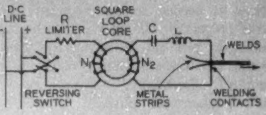

Fig. 4. Stitch-welding system

The system of Fig. 6 is suggested as a possible means to obtain two voltage pulses e_2 and e_3 in sequence, upon application of a current pulse I_1. Kirchhoff's laws for magnetic circuits implemented by some dynamic core information, perhaps simplified to the analytical form $H = H_c + K\,d\phi/dt$, yield a straightforward algebraic treatment resulting in significant predictions, while the **B-H** idealization with infinite and zero permeabilities, or its modification into a rectangular loop of fixed width, would not be fruitful. (It is interesting to point out here that an eddy-currentlike dynamic behavior appears also in ceramic materials in which eddy currents do not flow.)

Empirical core-reset functions, relating $\mathfrak{F}$, ϕ, and $d\phi/dt$ through flux swings from pronounced saturation, have been suggested by Feth,[11] from certain methods of dynamic testing on grain-oriented Ni-Fe alloys. These functions are intended to supply the missing link in the system of equations (Kirchhoff's voltage equations for the various meshes and mmf expressions for the various cores) describing the reset of all amplifiers examined so far; i.e., complete analytical treatments of those systems are made possible. It is not suggested here that these treatments are indispensable in questions of practical design; the point is that the student, aware by now of the general problem in its broad terms, may revert to simplified treatments, with some mature appreciation of what he is doing and why. In particular, he will be able to rise above the question as to whether the magnetic amplifier is a voltage-controlled or a current-controlled device and, in his work, will choose whatever idealization of the controlling action seems most pertinent.

The amplifier circuit of Fig. 7 is an instance in which the choice of one or the other of these two ways of thinking is prescribed by the operating specifications. In this amplifier the gating operation is based on the use of supply voltages considerably larger than twice the normal voltage of one core. Hence, in the absence of signal, both cores race simultaneously in each half-cycle from an initial saturation towards the opposite saturation, firing simultaneously before the end of the half-cycle, with zero output. The function of the signal is to unbalance the times at which the two cores saturate; output is obtained by transformer action in each half-cycle during the interval in which one core is already saturated while the other is not.

In a fast-response amplifier described by Hill and Fingerett,[12] the signal is the rectified voltage of an a-c transducer. The smallness of the mmf requirements of unsaturated cores justifies a straightforward use of the voltage equations to describe the operation, neglecting voltage drops of magnetizing currents, i.e., using the "extreme" core idealization.

On the other hand, in a low-level application analyzed by Frost-Smith,[13] the signal is a constant current I_c obtained, for instance, from a thermocouple or a photocell through a choke or a parallel inductance-capacitance combination. Here the extreme core idealization, or this together with the assumption of a rectangular major loop of fixed width, would lead to absurd conclusions, since the difference between the mmf of the two cores $\mathfrak{F}_1 = N_g i_g + N_c I_c$ and $\mathfrak{F}_2 = N_g i_g - N_c I_c$ prescribes the difference in the firing angles. Milnes' 3-zone representation may be used in this problem; more modern core-reset functions or their idealization in the form of a parallelogram fitting a suitable major loop (e.g., for sinusoidal flux swings between $\pm\phi_s$, at a frequency increased so as to obtain appropriate values of $d\phi/dt$ at the various ϕ's) may be preferable in a compromise between accuracy and timing of these studies.

It may be interesting to examine also the final version of this amplifier involving the use of two rectifiers λ' and λ'', connected back to back in parallel in the output circuit. This is an instance in which a symmetrical nonlinear resistance-like device is used to ensure balanced output, in remarkable similarity to some versions of Morgan's BRA single-core push-pull circuits.

THE 2-CORE SATURABLE REACTOR AND RELATED CIRCUITS

Self-saturating doublers and center taps, etc., with low control impedance may be considered next, either directly in terms of their circuit equations or following the classic approach which derives them from the 2-core simple saturable reactor.

The saturable reactor with zero control impedance may be treated, starting from the opposite end, i.e., from the case of infinite control impedance, reducing then the control impedance to a finite resistance $R_c > 0$, and ultimately arriving at the limiting case $R_c = 0$. This is suggested to prevent misunderstandings, detected in practice, concerning the meaning and use of the assumption $R_c = 0$.

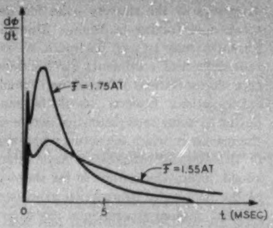

Fig. 5. Core-reset voltages upon application of constant reversing mmf $\mathfrak{F}$ to saturated core

As a "warm-up" for all this the waveform of the current i_g may be investigated in the simple system of Fig. 8(A). With some insight, the steady state may be described directly, but students, in this and many similar instances, may find it difficult to "jump into" the steady state directly if no starting information is supplied concerning the instantaneous values of the variables at some time in the cycle.

Ramey's philosophy,[14] of arriving at the steady state from a transient initiated from specified initial conditions, finds here a particularly simple application, i.e., at some arbitrary time, the switch S is closed and the ensuing processes are followed. (To avoid distracting issues of dynamic core properties etc., a numerical instance may be chosen in this problem in which $N_c I_c$ is substantially larger than any mmf requirements of the unsaturated core.)

The 2-core system of Fig. 8(B) is next considered. With the h-circuit open, this is the d-c transformer for metering purposes which may be treated either by the transient approach (which, however, is not as simple here as in the earlier case) or proceeding from the case of zero output circuit resistance to cases of finite output resistance as is done by Storm in chapter 8 of his book.[15]

Already, it is here seen that the extreme core idealization dictates the relation between instantaneous (and thus also half-cyclic) values of the ampere turns of control and gate circuit, if no simultaneous saturation of the two cores occurs at any time in the cycle. Volt-time area considerations (i.e., the use of voltage equations) remain necessary to examine the core flux, to determine the limits beyond which simultaneous saturation of the two cores disrupts the d-c transformer operation. The even-harmonic voltages induced in the circuit h, when open, are easily determined, and the operation of even-harmonic modulators into systems of infinite input impedance is understood.

The operation is modified when the h-circuit is closed. Simple manipulations prove the equivalence of this system to that of Fig. 8(C) where $R_c = R_h$ (if, for simplicity $N_h = N_c$) and $E_c = R_c I_c$. The control current i_c is then $i_c = I_c + i_h$. The study of this new system (i.e., the general series saturable reactor, with $R_c > 0$) is straightforward in terms of the voltage equations and of the core mmf expressions if the extreme idealization of core properties is accepted (and only resistive loads are considered).

Simple results are obtained if a rectangular gate voltage is assumed with a d-c control voltage E_c or if sinusoidal full-wave rectified signals in phase with a sinusoidal gate voltage are considered. The practical case of sinusoidal gate voltages and d-c control voltages inherently leads to more cumbersome solutions, exhaustively treated by Barker.[16]

At this point, the students recognize that solutions simplify conspicuously if E_c and R_c happen to be reasonably small with respect to $V_g N_c / N_g$ and $R_g (N_c / N_g)^2$ and thus they may appreciate the classic zero-control-resistance treatment of Storm in its meaning and usefulness, with a healthy understanding of the more general situation from which this limiting case has been approached.

Extrinsic feedback up to 100% may now be introduced, with discussion of algebraic equivalence of the latter circuit and of the doubler, and with mention of the different points of view in the choice of what should be considered as the basic amplifier. Perfect rectifiers may be assumed at first, to avoid the confusion of issues; leakage effects are introduced most easily at a later time.

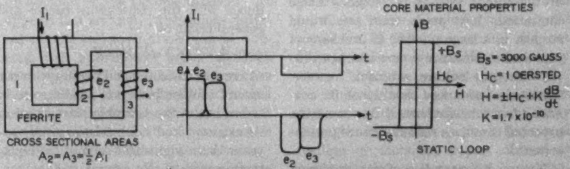

Fig. 6. Generation of pulses with multiaperture core

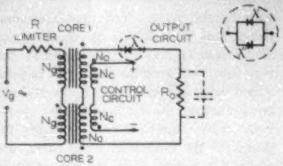

Fig. 7. Amplifier with even-harmonic output

The increasing need for more realistic core representations appears soon in this process. One will not say that the doubler with perfect rectifiers "theoretically has infinite gains, but practically this isn't so," recognizing rather that infinite-gain notions arise from an absurd extension of the use of simplifying assumptions that were acceptable perhaps in other situations for certain modest aims. Conceptual improvements upon the results of the extreme idealizations may be shown by the use of the 3-zone representation of Milnes,[1] which postulates a large but finite permeability for the unsaturated cores. The finite gains of the 100% feedback saturable reactor are justified in this way and the gradual transition from the controlled-current-source character of the saturable reactor to the voltage-output character of the doubler is also seen clearly.

This representation, of course, does not express the memory feature of square-loop cores, as it implies $\phi=0$ when $\mathfrak{F}=0$, but memory is not a first-order feature in the operation of these devices. In a better adherence to the measurable properties of modern cores, Storm's representation may be used as introduced by him in chapter 15 of his book.[16] His assumption, $\mathfrak{F}=0$, when $d\phi/dt=0$ for the unsaturated core, may be modified with the speculations on dynamic and static major loops of Jackson, et al.[17] Tentative criteria are thus obtained concerning the half-cyclic mmf of control.

The main stumbling block for more accurate predictions is recognized in our present inadequacies to express the processes that take place in the time interval in the half-cycle while the bottom of the minor loop is traversed. These limitations hurt more than one would suspect in a large number of problems of practical significance even with regard to the innocent-looking saturable reactor. These circumstances should not be concealed from the students if they are to be expected to make a reasoned use of present criteria.

Now, a different line of attack is suggested, using experimental transfer characteristics as the starting point for the solution of further problems. This information may be used backward, to obtain numerical coefficients for fictitious core representations of further use. Such extrapolations, however, should be supported by some semiqualitative notion of the manner in which the actual properties of the physical components have intervened, instant by instant in the shaping of the half-cyclic information expressed by that original experimental characteristic.

Experimental transfer characteristics are used more directly and quite simply in a large number of problems of design, e.g., to predict effects of degrading or upgrading of rectifiers or of negative or positive feedbacks of other kinds. Again, awareness of the nature of the instantaneous phenomena, as detected by oscilloscopic observation, is needed to prevent misuses of these simple criteria.

Properly measured transfer characteristics supply also the information needed for predictions of transient response. Outputs transients resulting from step changes of signal voltage, signal resistance, loading or line voltage, or frequency are related directly to corresponding changes of the preset flux value ϕ_p throughout the transient. These changes are expressed in the differential equation of the control circuit, introducing half-cyclic integrals as time variables.

It happens that the steady-state transfer characteristic, relating the gross half-cyclic voltage output V_0 (inclusive of the voltage drops in the gate-winding resistances) to the control voltage E_c, offers also a welcome means of expressing $\Delta\phi_p/\Delta I_2$ in the equation, since $\Delta\phi_p/\Delta I_c$ is proportional to the slope $\Delta V_0/\Delta E_c$ of the transfer characteristic, at any value of the half-cyclic V_0. This consideration applies for all magnetic amplifiers of this kind, from the simple saturable reactor to bistables, and opens the way for the integration of the first-order differential equation.

When the static gross voltage-gain $\Delta V_0/\Delta E_c$ is practically constant over the range of outputs considered, the resulting equation is one with constant coefficients and the amplifier time constant τ is introduced with the remarkably simple and general result of

$$\tau=\Delta V_0/\Delta E_c\times N_c/N_g\times 1/2f$$

where τ is in seconds and f is in cycles per second. When both gate windings are in series, i.e., in the saturable reactor and in its extrinsic feedback variations, $2N_g$ appears in the right-hand side of the equation instead of N_g. As is well known, obvious modifications of the general result arise when other circuits, of bias, etc., are present to further couple the two cores.

Every transfer characteristic of the slope $\Delta V_0/\Delta E_c$ applies for steady-state operation, after the step change of the variable that gave origin to the transient. The latter may be known directly or may be obtained from other available characteristics, or it may be predicted from core properties; the inadequacies of the latter procedures, of course, affect also the corresponding prediction of transient response.

The same results are obtained for the time constant of the amplifier proper, when feeding into rectified inductive-resistive loads with discharge paths. For inductive-resistive a-c output loadings, a transfer characteristic obtained from rectified terminal voltage measurements does not supply direct information on the half-cyclic flux swings; predictions of over-all transient behavior may be obtained still from direct steady-state measurements of these flux swings at various I_c's under pertinent loading conditions.

The simplicity of this approach and the results are obscured if that unfortunate concept, the figure of merit, is introduced prematurely in the transient problem. This is true because the concept is one step more remote from the essential mechanism of all magnetic amplifiers (saturable reactor included), i.e., the half-cyclic output voltage is the quantity truly controlled by the absorption of a part of the total half-cyclic volt-time integral of the supply voltage in the way of half-cyclic swings of core flux. Of course, the student will have understood by now that magnetic amplifiers are power amplifiers and that power gains and figures of merit are quantities of foremost practical interest. But this is not a reason for giving untimely emphasis to the latter concept in the transient problem.

So-called transportation lags may be discussed if it is recognized that reasonings in terms of half-cyclic averages inherently do not allow for short-time resolutions. Methods of measuring the transient response may be described.

When half-cyclic values are considered as the time variables of the problem, difference-equation methods suggest themselves; some information on the essence of these methods should be given the student (e.g., to enable him to understand some of the recent literature) considering them as a way of thinking which is appropriate and elegant.

Presently, much work is being done to describe the dynamic behavior of the magnetic amplifier, not only as a system component but also within itself, in the

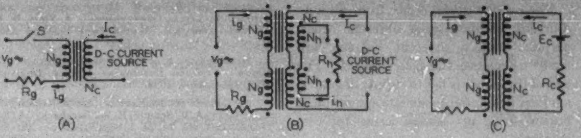

Fig. 8. Introducing the series-connected saturable reactor with finite control resistance $R_c > 0$

language of feedback theory. Expressing a recognized pattern of physical behavior in a different language is often beneficial as this can lead to different points of view and thus also to different and newer applications. However, there is a danger in this: the students, carried away by the relative ease of block diagram and transfer function techniques, should not lose sight of the actual physical phenomena only partially expressed in these treatments.

The transient treatment does not account for delaying effects of instantaneous currents that may be induced to flow at various times in various paths, resulting in a delay of over-all response, with well-known differences of response in building-up and building-down transients, especially in the doubler, and with limitations of the meaningful extension of that treatment to fast transients. While the treatment of these effects are most difficult, their semiqualitative recognition (e.g., in terms of Lenz's law) will assist the student in his later empirical work to appreciate, for instance, the influence of gate-winding resistances in these transients.

Also gains and time constants obtained independently for two amplifiers may fail to give reliable clues for a 2-stage system resulting from their combination. Evidently this is because the instantaneous constraints appearing in the interconnection are not expressed in the half-cyclic average information previously mentioned. This recognition at least opens the way to more pertinent experimentation in empirical developments.

Push-pull and polyphase combinations and self-balancing amplifiers, etc., remain to be examined. Students, commonly familiar with similar techniques in vacuum-tube electronics will recognize to some extent the basic ideas of circuitry. The difficulties met before in the attempts to describe the operation of conventional single-ended amplifiers multiply rapidly in these situations, but it is not within the scope of the training course to supply quick answers to complex questions which are as yet largely unsolved. The semiqualitative consideration of design found in the books of Geyger,[18] Storm, and Milnes, are a good starting point for a reduction to practice. The designer is on his own from there.

To conclude the course, some brief survey may be given of the methods used in the study of amplifiers with cores of gradually varying differential permeability, as presented years ago, e.g., by Johnson[19] and by Beaumariage, et al.[20] A single-valued analytical approximation of the normal magnetization curve and the assumptions of zero control resistance and zero load resistance are used; the concept of firing does not occur in these treatments and the influence of loads is expressed by load lines of sinusoidal a-c theory. These earlier approaches, dictated by the properties of the core materials then most readily available, are rather unsatisfactory in view of the assumptions. But improvements are most difficult analytically and this explanis the place these methods still hold in some European and Russian literature.

The student may gratefully recognize at this point that the strange features of square-loop cores that may have shocked him at first are really most beneficial, performance considerations aside, as leading to more satisfactory and interesting ways of thinking.

Closing Remarks

The program presented is not intended to teach special technologies. The semiempirical state of the art and the many as yet unanswered questions appearing in any development of magnetic amplifiers suggest that it may be necessary, first, to clarify the pertinent physical laws and phenomena of these systems in relation to the essential properties of the basic components. Some subtle issues should not be avoided, which conceivably one would prefer to ignore, but which unfortunately remain of primary concern to anyone interested in quantitative results of design.

Comparatively simple physical instances may be introduced in a coherent sequence, so as to stress a few concepts and methods at the time, with proper emphasis on the appraisal of the simplifying approximations that may or may not be accepted in the various instances. It appears that a variety of seemingly different circuits and applications can be covered with a consistent logic, (although "coverage" should not be considered the essential aim), and that lively and critical habits of thought can be developed which are indispensable for a competent use of the literature and later empirical work.

For this, lectures to a passive audience should be avoided; information passively acquired can seldom be put to use; rather they may result in a dangerous acceptance of ill-digested half-truths when novel and unconventional concepts are unfolded. Many of the instances may be presented as problems, with the assistance of a few restrained hints, leaving the students to search for suitable approaches with the help of some simple experimentations as needed, and then co-ordinating their findings in a more general perspective. In other instances, the students may be invited to establish critical comparisons of of the content of technical papers describing devices unrelated perhaps from the point of view of applications but embodying some essential common feature.

A dozen problems, distributed over about as many weeks, and solved with the support of weekly half-day laboratory sessions and 2-hour class meetings have proved sufficient to cover most of the area described in a recent graduate course at the Carnegie Institute of Technology. The same general approach has been tried also in industry; dealing with groups of engineers, initially not familiar with the magnetic amplifier, but otherwise mature and conversant with questions of development and the design of electric devices, the scholastic "home problem" approach was felt less necessary, but it was still preferred to lead the audience into discussion, rather than "lecturing" it. In either case the results seemed quite good as evidenced by the wealth of original thought, with germs of ideas of the kind that may evolve into technical papers or patent disclosures and worth-while products.

It may be added that students approaching this peculiar field with open mind, considering magnetic amplifiers as electromagnetic systems that obey the general laws of electromagnetism with particular twists dictated by the special properties of the components, did not have serious conceptual difficulties at any time. This was not the case, initially, for students who had previous misconceptions and biased points of view, easily arising in this field, e.g., from the casual reading of technical papers chosen at random or from unwarranted generalizations as a result of brief experience.

The outline given is far from unique; different instances in a different order, perhaps with a different balance, are likely to achieve the same results. The aim of this paper is not to supply dogmatic answers to a difficult educational problem but to bring up certain issues for discussion.

Automatic Control of Electrical Precipitation Rectifiers

H. E. VAN HOESEN
NONMEMBER AIEE

H. J. WHITE
MEMBER AIEE

H. J. HALL
ASSOCIATE MEMBER AIEE

THE PRIMARY objectives of an automatic rectifier control in electrical precipitation are to increase long-term collection efficiency, eliminate need for operating personnel, and insure maximum utilization of equipment under the widely variable process and operating conditions found in most applications. A review of the literature[1–3] indicates that a number of automatic control schemes have been devised for precipitator control. Most of these systems never received widespread usage because of inherent limitations. Some required expensive, complicated mechanisms which were difficult to maintain or adjust. Others were unable to provide the correct control range, response or reaction to meet the variety of operating conditions encountered. More recently, improved equipment based on electronic techniques has been developed and is now in successful commercial use.[4]

Experience with automatic rectifier controls for electric precipitators since 1949 has shown the desirability of incorporating voltage, current, and spark-rate as control parameters. Extremely rapid response is essential to cope with sudden changes in precipitator electrical conditions which commonly occur in practice. This paper describes a new automatic control system which meets these requirements and which is broadly applicable to industrial electrical precipitation.

Electrical Characteristics and Control Requirements of Precipitators

Before describing the new control system, it is well to review electrical precipitator operation and the control requirements. The critical dependence of collection efficiency on the operating peak voltage and sparking rate as illustrated in Figs. 1 and 2, is characteristic of electric precipitators. On account of the steep voltage-current characteristic of the corona discharge, small changes in voltage can produce large changes in current and power. This is especially significant in the region of the sparking potential where the corona power increases at a rate at least four or five times faster than the peak voltage. High voltage and high corona power promote high collection efficiency. On the other hand, excessive voltage causes a rapidly increasing sparking rate which reduces the efficiency. Obviously, there exists a balance between these opposing factors where the gains obtained by increasing the voltage are offset by the losses resulting from sparking. For our purposes, it is important to differentiate between a spark and a power arc. A spark, illustrated in the precipitator voltage oscillogram of Fig. 3, is a random, transient voltage breakdown of short duration, considerably less than 1/10 of a voltage cycle of the power frequency. By contrast, a power arc is a continuous heavy-current discharge which lasts from a few cycles to hundreds of cycles. Whereas a spark has only a slight effect on precipitator collection, a power arc is disastrous to performance and should be avoided by proper circuit design.

In practice, electrical characteristics of precipitators vary widely not only between installations, but also change with time on any given installation. Plant process variations and electrode dust deposits affect voltage, current, and sparking characteristics. All precipitator operation can be classified under three general cases.

1. Current limited: The precipitator may have low impedance characterized by heavy current, low voltage, and little or no sparking. The appropriate control action in this case is to provide maximum current flow, limited only by rectifier capacity.

Paper 58-229, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, N. Y., February 2–7, 1958. Manuscript submitted October 14, 1957; made available for printing November 25, 1957.

H. E. Van Hoesen, H. J. White, and H. J. Hall are with Research-Cottrell, Inc., Bound Brook, N. J.

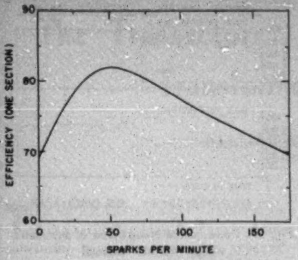

Fig. 1. Per-cent efficiency as a function of average sparking rate for a typical fly-ash precipitator

2. Voltage limited: The precipitator may have relatively high impedance, with low current, high voltage, and little or no sparking. Here the best action is to raise the precipitator voltage as high as possible, consistent with rectifier ratings.

3. Spark limited: Under this condition, precipitator power input is limited by sparking below the current and voltage limits of the rectifier. Optimum collection is achieved by maintaining a reasonably constant spark-rate, typically 100 sparks per minute per rectifier set.

The New Automatic Control System

The new automatic control system is based on the three general cases of precipitator operation outlined in the foregoing. Design requirements include dynamic, wide-range control with fast transient response and high reliability. A simplified block diagram of this system is shown in Fig. 4. Two feedback control loops are used: one for current and one for spark-rate. These control loops operate independently or co-operatively according to the instantaneous control requirements. The voltage level control provides an upward bias which tends to raise the rectifier transformer voltage to its rated value. Error signals from the two feedback loops modify the voltage raise function to establish system equilibrium at a dynamic control point.

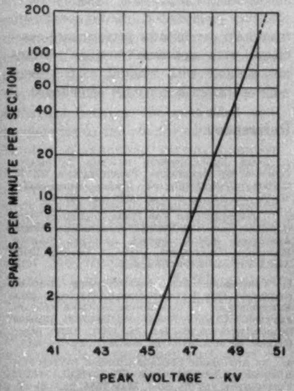

Fig. 2. Variation in sparking rate with operating peak voltage for a representative fly-ash precipitator

A saturable-core reactor is used as the control element to regulate power input to the high-voltage transformer and rectifier. Control of this reactor is accomplished through a grid-controlled thyratron driver which performs the function of a stable high-gain d-c power amplifier. The three control signals, voltage, current, and spark-rate, are injected through the master comparator to the driver. This comparator functions as a mixer which provides an output signal equal to the sum of three input signals.

Current control is accomplished through the current signal generator which converts an a-c signal to an error signal proportional to the deviation from the current control point. Primary current is sensed by the voltage drop across a small resistor in the primary circuit. The current signal can be taken from the secondary circuit if desired.

The spark-rate signal generator converts spark signal pulses to a d-c error signal proportional to the deviation from the desired spark-rate. A simplified schematic circuit of the spark-rate control is shown in Fig. 5. Spark transients are sensed across high-voltage transformer primary winding. These pulses are separated from the a-c component by a spark detecting network which passes only spark pulses. These pulses fire switch tube *V*1 in the pulser circuit, composed of elements *V*1, *L*1, *C*1, and *R*1. Each time *V*1 fires, it discharges condenser *C*1 momentarily. The following charging current for *C*1 produces a voltage pulse across *R*1. This voltage pulse is integrated by the network composed of *R*2 and *C*2 to obtain a voltage proportional to the average spark-rate. The integrated voltage V_A appears across *R*3 as the spark signal voltage. Time constants *R*1 *C*1, *R*2 *C*2, and *R*3 *C*2 must be properly selected to obtain proper integration and control action.

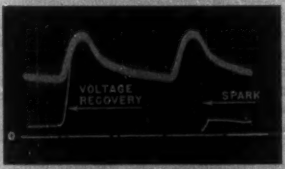

Fig. 3. Precipitator voltage oscillogram for half-wave rectifier connection illustrating rapid recovery after sparking recurrent sweep

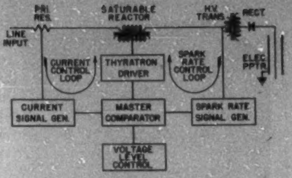

Fig. 4. Block diagram for automatic rectifier control system

To obtain an error signal it is necessary to compare the spark signal voltage with a reference preset to the desired spark-rate. This is accomplished in the comparator circuit composed of *V*2, *R*3, *R*4, and *R*5. The reference voltage V_B governing spark-rate is preset by potentiometer *R*4. Note that reference voltage V_B is in opposition to spark signal V_A. Error output voltage V_C appears across *R*5 only when the signal voltage V_A exceeds the reference voltage V_B. Under this condition, tube *V*2 conducts and an error voltage proportional to the deviation, appears across *R*5. This error voltage V_C modifies the raise bias on the thyratron driver to maintain a fixed spark-rate level.

The current control system operates in a similar manner. In essence, an a-c signal voltage proportional to primary current is rectified, filtered, and compared with a preset reference value to obtain a current error signal.

The new automatic control unit is

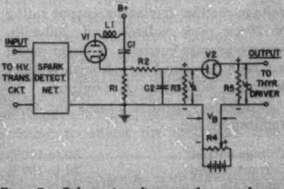

Fig. 5. Schematic diagram for spark-rate signal generator

V_A—Spark signal
V_B—Spark reference
V_C—Error signal

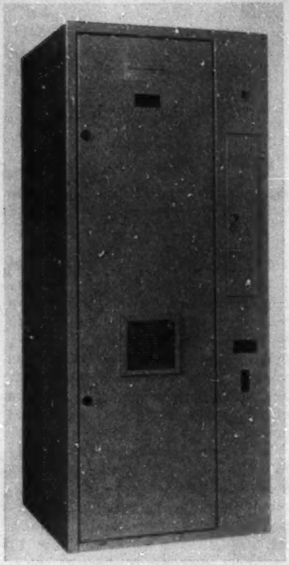

Fig. 6. New automatic control assembly for 230-milliampere rectifier

shown in Fig. 6. Any number of these units can be controlled from a single remote "on-off" switch, an arrangement which is desirable in some installations. Individual service breakers are provided to de-energize each control and its associated high-voltage rectifier. Three factory preset adjustments, voltage level, current level, and spark rate, are provided on each unit. These adjustments may be easily reset in the field if necessary to meet unusual conditions.

This control has been developed primarily for use with 60 cycles per second power systems. The model illustrated is designed for use with a high-voltage rectifier having an output rating of 70-kv peak voltage and 230-milliampere average current. A larger model has been developed for use with rectifier sets up to 500-milliampere output.

Satisfactory control ranges for most applications are:

Voltage output	50 to 100%
Current output	20 to 100%
Spark-rate	50 to 500 per min.

Voltage recovery after a precipitator spark is achieved in one cycle. Transient response time of the current and voltage control is fast enough to insure complete control under all operating conditions. Even for abnormal conditions, such as internal short circuits in the precipitator, the control will automatically limit current at the preset maximum rating, without trip-out or other disturbance. However, a signal system is incorporated to indicate these abnormal conditions. Over-all power conversion efficiency of the complete rectifier system, including all fixed losses, is 70 to 75% at rated output.

Application and Performance

The new automatic control system can be applied advantageously to most industrial precipitator applications such as cleaning of boiler, metallurgical, cement kiln, and chemical process gases. Practically all industrial furnace and process gases are subject to wide variations in gas flow, temperature, humidity, dust concentration, dust resistivity, and other factors which influence precipitator operation. The automatic control tends to compensate for these variations, thereby maintaining optimum precipitator performance.

Field tests on these new control units have been in progress since early 1956 on fly ash and metallurgical applications. The original experimental model has provided continuous trouble-free operation since first installed and has become a permanent part of the plant equipment. Standardized production and commercial application of the new control have been in effect since January 1957. Control levels on voltage, current, and spark rate have been successfully preset at the factory and operation has been entirely satisfactory to date.

The field tests have shown that improved precipitator energization and higher collection efficiencies associated with higher corona power are achieved with this automatic control. Fig. 7 shows a reproduction of recording voltmeter and ammeter charts made on one rectifier set on a fly-ash precipitator to compare manual and automatic control. Because of changes in boiler operation and coal burned, the manual control was normally operated at a moderate power level in order to prevent over-current trip-outs of the rectifier. In contrast, the automatic control operated at substantially higher power because of its ability to rapidly and continuously correct rectifier settings to meet changing load conditions. The average power input to the precipitator from this rectifier set was 5.6 kw with the manual control and 9.3 kw with the automatic control, an increase of 65%. Subsequent periodic measurements have shown this power increase typical.

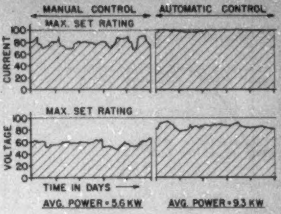

Fig. 7. Performance comparison of automatic versus manual control

Experience on industrial installations has indicated this new control has intrinsic value extending beyond precipitator energization for which it was designed. In certain instances, it is possible to correlate automatic control action with plant process variables. Thus the precipitator control action can be applied as a control parameter for the process variable to provide over-all automatic system control. This not only improves precipitating conditions, but may also increase the uniformity and quality of the product produced.

Conclusion

In conclusion, the automatic rectifier control system described provides optimum precipitator energization under the fluctuating load conditions normally encountered in practice. It is not a substitute for a properly designed high-efficiency precipitator. But it does insure maximum precipitator performance associated with optimum rectifier settings not possible with manual control even with operators in constant attendance.

The Transactor: A Self-Saturated Transformer—Part I

ALLEN B. ROSENSTEIN
MEMBER AIEE

THE OPERATION and characteristics of the saturable transformer[1] and the saturating magnetic reference type of transformer[2] have been presented in past articles. The advantages and shortcomings of the self-saturating magnetic amplifier circuits have been explored at length. It is the purpose of this paper to start with the elementary concept of a magnetic switch and develop a magnetically controlled self-saturated transformer. The magnetic system developed possesses many of the desirable operational characteristics of both the saturable and saturating transformers. An adjustable a-c or d-c output is obtained which is also voltage-stabilized. At the same time, the self-saturating transformer retains the gain and response characteristics of the self-saturating magnetic amplifier, although a number of the disadvantages of the magnetic amplifier are eliminated.

Magnetic-Amplifier Shortcomings

The shortcomings of the conventional magnetic amplifier inherently arise from the fact that the saturable reactor (or reactors) is basically connected in series with the load. The reactor acts as a magnetic gate which subtracts a predetermined number of volt-seconds from each half-cycle of a-c source voltage, allowing the remainder to appear across the load. The output thus becomes the difference between the controlled volt-seconds set in the reactor core and what is often a randomly varying quantity, namely, the a-c line voltage. Variations in line voltage become a direct cause of drift and/or noise in the amplifier output. Because of the series form of connection, the magnetizing current of the reactors must flow through the load, giving a quiescent load current. As this quiescent current is often a function of the a-c supply voltage, interstage coupling can thus also present a practical problem. Because of the finite magnetizing current of its reactors, it becomes difficult or impossible for the magnetic amplifier to work into an open circuit or very-high-resistance loads. This sometimes becomes a nuisance for, should the load resistance tend to vary widely, a substantial bleeder resistance is usually required to restrict the variation of output voltage.

Fundamental Magnetic-Switch Operation

The fundamental mechanism of the magnetic amplifier is usually presented with the assumption of a perfect magnetic core. Fig. 1, the "perfect" core, possesses a 2-zone **B-H** characteristic offering infinite permeability when the net ampere-turns impressed upon the core are zero, and zero permeability when the net ampere-turns do not equal zero. With the assumption of perfect cores, the saturable reactors may now be considered as 2-position magnetic switches with a built-in volt-second memory. In their capacity as switches, the reactors in one position (net ampere-turns ≠0) will cause all reactor winding to be short-circuited. In the second position or mode II (net ampere-turns = 0), the reactors appear as perfect transformers, transforming the impedance of the control circuits into the power or gate circuit. In the "game" of magnetic-amplifier circuitry, it becomes our objective to arrange control windings in such a way that negligible induced currents flow in the control windings during this second mode. The control winding are so connected that the voltages induced in them are either self-cancelling, blocked by a high impedance, or bucked out by auxiliary sources. In any event, with negligible induced currents flowing in them, the control windings of the magnetic amplifier will reflect a very high impedance into the gate circuit during mode II. If the magnetic amplifier has been connected in series with the load, as in one of the conventional circuits, the high impedance reflected from the control circuit into the gate windings during mode II will cause most of the applied a-c supply voltage to appear across the reactors.

Parallel Output

Fig. 2 shows the a-c self-saturating magnetic amplifier or "doubler." During mode II, with practically all of the a-c supply voltage appearing across the reactors, one reactor will be taken toward saturation, while the second reactor will be reset by the control voltage. During the next half-cycle, the volt-seconds absorbed from the a-c line by the reset reactor will be dependent upon the volt-seconds that had been reset into it by the control in the first half-cycle.

As noted previously, the output voltage across the series load element R_L is equal to the difference between the volt-seconds supplied by the line and the volt-seconds absorbed by the controlled element, the reactor. Also, it is interesting that, while variations in a-c voltage will affect the output, the average voltage per cycle dropped across the reactors is dependent only upon the control signal.[3] Since the average potential across the reactors is less subject to random variations than the potential across R_L, one is led to consider the possibilities of connecting the output load in parallel with the magnetic amplifier instead of in series; see Fig. 3(A).

The conclusions typified by Fig. 3 may also be reached by starting with the saturating voltage-stabilizing transformer; see Fig. 4(A). Saturating transformers using high-quality, square hysteresis loop core materials have been manufactured for some time. The transformer and a-c supply are deliberately proportioned so that the supply always furnishes more volt-seconds per half-cycle than the magnetic core of the transformer can support. The core of the saturating transformer therefore is driven in each half-cycle from negative to positive saturation (or vice versa) by the supply. The transformer core flux deviation per cycle becomes a fixed constant value. Consequently, the volt-seconds induced in the transformer secondary winding are independent of variations in load resistance or a-c supply voltage. Since the core of the transformer saturates before the end of each half-cycle, the saturating transformer appears as a dead short circuit twice every cycle. The element Z_L is added for the sole purpose of limiting these short-circuit currents.

The saturating transformer serves as a very useful and simple dynamically stable voltage source. However, its output is not readily controlled unless some method is found to adjust the total core flux

---

Paper 58-178, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Allen B. Rosenstein is with the University of California, Los Angeles, Calif.

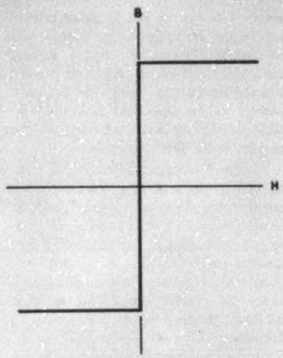

Fig. 1. Idealized B-H characteristics

change per half-cycle. To control the induced secondary volt-seconds per cycle, insert a diode in series with the primary of the saturating transformer. The a-c line can now cause a flux excursion in only one direction. To reset the core flux during the following half-cycle, add a control winding to the transformer, along with a control impedance and control voltage; see Fig. 4(B). The control winding will thus reset the core flux to any desired level. The control thereby governs or predetermines the volt-seconds, which may be coupled into the secondary during the following power half-cycle. To decouple the load from the flux-resetting control voltage, a diode is added in the transformer output winding. Again, the volt-seconds induced in the secondary will be independent of variations in the a-c supply voltage.

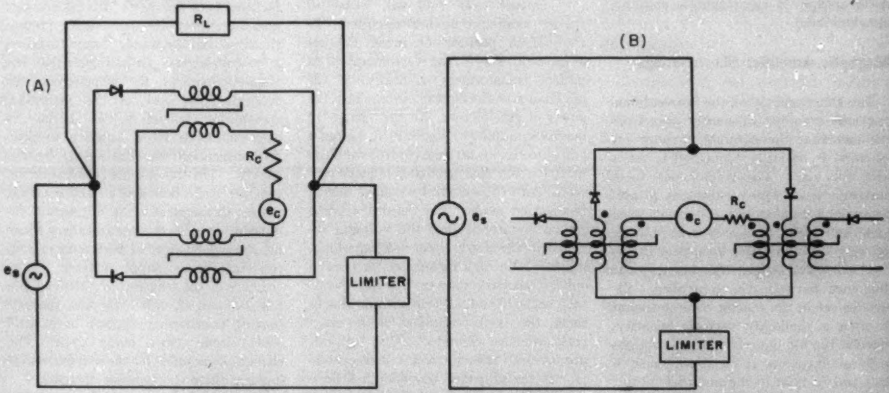

Fig. 3. A—Self-saturating a-c magnetic amplifier with shunt (parallel) loading. B—Full-wave transactor

The Transactor

Since the transformer now plays the dual role of a transformer and a saturable reactor, it is proposed that it be called a "transactor" and it shall be so referred to in the remainder of this paper. Z_L continues to play the role of a current limiter after the transactor has saturated; it shall hereafter be referred to as the "limiter."

The half-wave self-saturated transactor of Fig. 4(B) might be considered the fundamental building block of all transactor circuits. It will display a number of desirable characteristics, including:

1. Half-cycle response.
2. An output which will be largely independent of a-c supply variation.
3. Output circuit isolated from the a-c supply line (which means essentially magnetic coupling).
4. Output voltage independent of load impedance. (The transactor can work into an open circuit.)
5. Low quiescent output voltage which is independent of the a-c line and output loading.

In keeping with magnetic-amplifier tradition, the analysis of the half-wave transactor will be developed in Part II of this treatise. In Part I, a detailed analysis of a full-wave transactor system is presented.

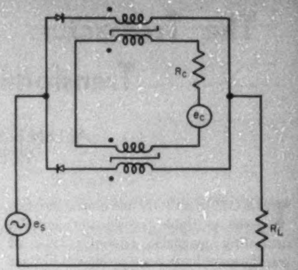

Fig. 2. Self-saturating a-c magnetic amplifier, doubler

The half-wave transactor of Fig. 4(B) is readily converted to a full-wave output by the addition of another saturable transformer and two rectifiers; see Fig. 3(B). Comparing the circuits of Figs. 3(A) and (B) it is seen that they are fundamentally the same. The transactor is intimately related to the shunt-loaded self-saturating a-c magnetic amplifier. In the transactor circuit, the load is transformer-coupled in parallel with the magnetic amplifier. Although the addition of the transformer secondary winding obviously reduces the power-handling capacity of a given core, it does offer certain advantages, including the convenience of interstage coupling and the

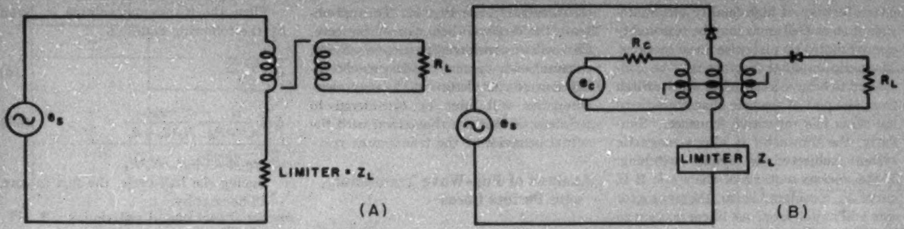

Fig. 4. A—Saturating transformer voltage regulator. B—Half-wave self-saturated transformer–half-wave transactor

elimination of the variations of IR (current-resistance) drop in the primary gate windings and rectifiers. The two transactor secondaries can also be readily connected in series, center tap, to give a full-wave d-c output, or in parallel to give a full-wave a-c output.

THE LIMITER

After the transactor saturates, some type of series-limiting device in series with the transactor primary is necessary to prevent the alternating current from reaching destructive values. Any of the linear circuit elements of resistance, capacitance, or inductance may be used. It is expected that for small-signal low-power transactors, resistors will be used as limiters for simplicity and minimum cost. Where higher frequency a-c carriers are employed, capacitors should be practical. In fact, with series capacitors, additional regulating action may be obtained by designing the system as a nonlinear series-resonating regulator. The transactor will resonate with the capacitor and saturate before the end of each half-cycle.

Where it is desirable to handle large amounts of power, the limitations of linear limiters are too well known to warrant further discussion. For the large power transactor the ideal limiter would be a nonlinear zero-power-dissipating limiter which would restrict the transactor primary current to instantaneous values only slightly in excess of those required for maximum power output. Several biased-reactor circuits suggest themselves, possessing characteristics closely approximating the ideal. If the limiters are properly constructed and biased, they will allow the transactor to operate from no load to full load without affecting the output voltage. However, the limiters would be set for a given maximum current, which would make the system self-protecting and even allow long-time short-circuiting of the transactor output.

Several variations in limiter circuitry will be described in Part II. For Part I the limiter will simply be an ordinary series-connected saturable reactor with very high control circuit impedance.

Circuit Analyzed

The full-wave transactor system which was analyzed and tested is given in Fig. 5. The behavior of the series-saturable reactor with high-control circuit impedance has been fully developed by others.[4] This series reactor has been shown to behave as a constant alternating current device. It supplies square waves of current of fixed magnitude to the load, which in this case is the transactor.

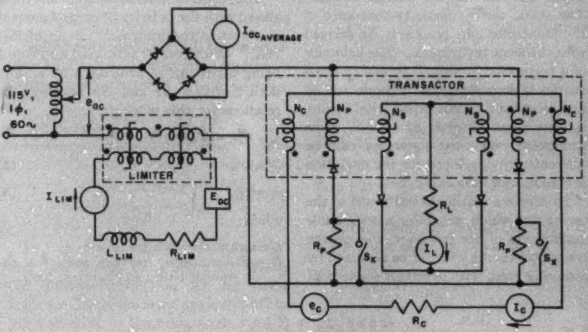

Fig. 5. Full-wave transactor schematic

The transactor shall act as a magnetically controlled saturable transformer and shall gate to the output a rectangular-pulse-width modulated wave. The width of the output wave shall be controllable from nearly zero to full half-cycle. For a given control setting, the output volt-seconds will remain constant under variation of load resistance a-c supply voltage, and limiter peak current. However, the height and consequently the width of the output pulse will vary although the area remains constant.

As a result of the choice of limiting circuits, for the purposes of this analysis, the alternating voltage source and the limiter may be replaced by an equivalent constant-current, square-wave generator. The choice of limiters will offer several advantages, not the least of these including:

1. An appreciable simplification of the complexity of the analysis.
2. A relatively linear transfer function when a d-c control signal is used.
3. A pulse-width modulated square-wave output which should be ideal for driving switching transistors or other stages of magnetic amplification.

Method of Analysis

It has been shown that the ultimate performance of the high-gain magnetic-amplification system is a direct function of its core material.[4] The static B-H characteristics of high-quality core materials such as Deltamax may be reasonably approximated by piecewise linear sections. Magnetic-amplifier reactors may be considered to behave as switches which switch from one part of the core characteristic to the other in a repetitive sequence. Similarly, the transactor is also a magnetic system subjected to cyclic switching. If the various sections of the static **B**-**H** curve are considered linear, the transactor core will switch from one linear portion to the other. The performance may then be represented by a sequence of linear equations.

Johannsen,[5] Bourne,[6] Hubbard,[7] Kikuchi,[8] Kusada[9] and others have successfully applied difference equations to magnetic-amplifier analysis. (Particular attention is called to Kusada's paper which analyzes the a-c doubler circuit.) The static and dynamic performance of the transactor can profitably be derived with the same techniques. The behavior of a transactor in any given half-cycle of output is dependent upon the amount of flux reset the core has experienced during the previous half-cycle of control. The transactor difference equations can be conveniently developed for the deviation in core flux for each half-cycle.

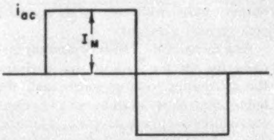

Fig. 6. Supply current wave form

To evolve a mathematical model of the transactor which will offer a reasonable explanation of its behavior, the chosen transactor circuit will first be analyzed by assuming cores with a perfect static **B**-**H** characteristic; see Fig. 1. To approximate the dynamic behavior of the core, they will be considered to possess a finite, constant eddy-current resistance. Modifications of the picture of the core characteristics will later be considered to reconcile further the theoretical with the actual behavior of the transactor.

Analysis of Full-Wave Transactor with Perfect Cores

Reference is made to the schematic. The limiter acts as a constant-current square-wave generator. The transactor will be analyzed on the basis of a constant-current square-wave source, see Fig. 6. The transactor core material is assumed to possess a perfectly square static **B**-**H** characteristic with zero hysteresis; see Fig. 1. The core material, however, possesses finite resistivity and therefore the dynamic **B**-**H** curve, because of core eddy currents, will have a finite separation between its ascending and descending legs.

Starting with zero bias current, both cores are always saturated if perfect **B**-**H** characteristics are assumed.

Mode I Operation

The control circuit switch may be closed with the polarity of control current as shown in the equivalent circuit of Fig. 7(A). With core II saturated and core I being taken out of saturation by e_c, and with rectifiers $S1$ and $S3$ blocked, the relations for this mode are:

$$e_c - N_c e_0 = i_c R_c \tag{1}$$

$$N_c i_c = i_e \tag{2}$$

$$e_0 = i_e R_e \tag{3}$$

where

e_0 = transactor volts per turn
R_e = effective eddy current resistance assuming 1-turn eddy current loop

Then, the transactor voltage is given by the following equation

$$e_0 = \frac{e_c/N_c}{A} \tag{4}$$

$$i_e = \frac{e_c}{AN_c^2R_c} = \frac{e_c}{N_c^2R_e + R_c} \tag{4A}$$

where $A = 1 + R_c/N_c^2R_e$.

During the half-cycle, the flux in core I will be reset by

$$\Delta_0 = \frac{1}{\omega}\int_0^{\pi} e_0 d\theta \tag{5}$$

Mode II Operation

When the polarity of the source current i_{ac} is reversed, the flux of core I will be driven toward saturation while the flux of core II will be taken out of saturation. With a small control voltage it will be assumed that rectifiers $S2$ and $S4$ must now block with rectifiers $S1$ and $S3$ conducting. The new equivalent circuit is shown in Fig. 7(B), the relations for which are

$$e_1 = i_{e_1} R_e \tag{6}$$

$$e_1 = \frac{i_{L_1} R_L}{N_s} \tag{7}$$

$$e_2 = i_{e_2} R_e \tag{8}$$

$$e_c + N_c e_1 - N_c e_2 = i_c R_c \tag{9}$$

$$N_c i_c - i_{e_2} = 0 \tag{10}$$

$$N_c i_c + i_{e_1} + N_s i_{L_1} - N_p i_1 = 0 \tag{11}$$

where e_1, e_2 = transactor volts per turn.

Since $i_1 = i_{ac}$, the six equations may be solved for e_1, e_2, i_c, i_{e_1}, i_{e_2}, i_{L_1}. Therefore during the interval in which the conditions of Fig. 7(B) prevail

$$e_2 = \frac{B}{1+AB}\,\frac{e_c}{N_c} + \frac{R_e N_p i_{ac}}{1+AB} \tag{12}$$

$$e_1 = -\frac{1}{1+AB}\,\frac{e_c}{N_c} + \frac{A}{1+AB}\,R_e N_p i_{ac} \tag{13}$$

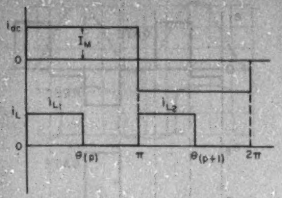

Fig. 8. Supply line I_{ac} and load I_L currents

$$i_{L_1}=-\frac{1}{1+AB}\frac{N_s}{N_cR_L}e_c+\frac{A}{1+AB}\frac{R_s}{R_L}N_sN_pi_{ac} \qquad (14)$$

$$i_c=\frac{B}{1+AB}\frac{e_c}{N_c^2R_s}+\frac{N_pi_{ac}}{N_c(1+AB)} \qquad (15)$$

$$i_{e_1}=-\frac{1}{1+AB}\frac{e_c}{N_cR_s}+\frac{A}{1+AB}N_pi_{ac} \qquad (16)$$

$$i_{e_2}=\frac{B}{1+AB}\frac{e_c}{N_cR_c}+\frac{N_pi_{ac}}{1+AB} \qquad (17)$$

where

$$A=1+\frac{R_c}{N_c^2R_s}$$

$$B=1+\frac{R_sN_s^2}{R_L}$$

When control voltage is applied, the flux level in each core is reset progressively lower each cycle until finally the minor loop reaches steady state.

It should be understood that in the course of each half-cycle, the mode of operation shown in Fig. 7(A) normally follows the mode illustrated in Fig. 7(B). At the beginning of each half-cycle, one core will be found saturated while the other will be unsaturated. Fig. 7(B) shows the originally saturated core (core II) being reset while the other (core I) is being carried by the load voltage toward saturation. Some time during the half-cycle, core I will saturate and short-circuit out all of its associated windings. The conditions of Fig. 7(A) will now prevail for the remainder of the half-cycle. For the Fig. 7(A) condition, however, it will be core I saturated and core II being reset. With the next half-cycle the role of the cores will be reversed: Δ_0 is obtained by integrating over a full half-cycle only for that initial half-cycle following application of e_c. For subsequent half-cycles the value of Δ_0 is found by integrating e_0 from $\theta(\rho)$ to π.

Although both equivalent circuits, Fig. 7(A) and (B), show R_L in two places, the actual circuit had only one R_L. The two R_L's are shown simply for convenience in drawing the equivalent diagrams. It is to be noted that only one transactor at a time will couple the load resistor R_L over to be fed from the current source. Fig. 8 shows current voltage waveforms for one cycle. Fig. 9 gives the dynamic **B-H** loop.

During one cycle the flux changes of one core are

$$\Delta_2=\frac{1}{\omega}\int_0^{\theta(p)}e_2d\theta \qquad (18)$$

$$\Delta_0=\frac{1}{\omega}\int_{\theta(p)}^{\pi}e_0d\theta \qquad (19)$$

$$\Delta_1=\frac{1}{\omega}\int_{\pi}^{\theta(p+1)}e_1d\theta \qquad (20)$$

Here the voltage e_2 is the reset potential across the core (corresponding to core II, Fig. 7(B)) during the first part of the cycle $0-\theta(p)$ before the other core has saturated; e_0 is the reset potential across the same core [corresponding to core I in Fig. 7(A)] during the rest of the half-cycle $\theta(p)-\pi$ after the other core has saturated. The setting potential is e_1 on the core [similar to core I, Fig. 7(B)] during the following half-cycle in the interval from π to $\theta(p+1)$ where the core saturates.

Since the total sum of the flux changes during one complete cycle is zero for both transient and steady-state operation,

$$\Delta_2+\Delta_0=\Delta_1 \qquad (21)$$

Substitute equations 4, 12, 13 into equations 19, 18, and 20; then into equation 21 (remembering that $e_c=E_c$ and $i_{ac}=I_M$).

$$\frac{B\dfrac{E_c}{N_c}+R_sN_pI_M}{1+AB}\int_0^{\theta(p)}d\theta+\frac{\dfrac{E_c}{N_c}}{A}\int_{\theta(p)}^{\pi}d\theta=\frac{-\dfrac{E_c}{N_c}+AR_sN_pI_M}{1+AB}\int_0^{\theta(p+1)}d\theta \qquad (22)$$

Letting $E_c/N_c=E_c'$ and $R_1N_pI_M=I_M'$, and performing the integration, yields the difference equation for the firing angle θ, relating the firing angle $\theta(p)$ of the pth half-cycle to the firing angle $\theta(p+1)$ for the $p+1$ half-cycle:

$$(A^2I_M'-AE_c')\theta(p+1)-(AI_M'-E_c')\theta(p)=(1+AB)\pi E_c' \qquad (23)$$

For the steady-state condition $\theta(p)=\theta(p+1)$

$$\theta(\infty)=\frac{(1+AB)\pi E_c'}{-(A-1)E_c'+A(A-1)I_M'}=\frac{\left(1+\dfrac{N_c^2R_s+R_c}{N_c^2R_s}+\dfrac{R_L+R_sN_s^2}{R_L}\right)\pi E_c'}{-\dfrac{R_c}{N_c^2R_s}E_c'+\dfrac{R_c}{N_c^2R_s}\dfrac{N_c^2R_s+R_c}{N_c^2R_s}I_M'} \qquad (24)$$

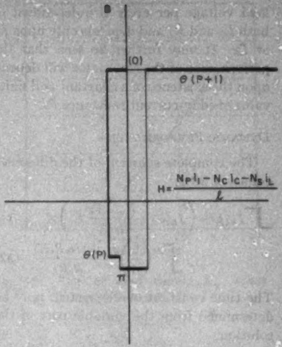

Fig. 9. Dynamic B-H loop

Under most operating conditions this reduces to

$$\theta(\infty)\cong k\frac{\pi E_c'}{I_M'} \qquad (25)$$

In any given half-cycle the average load current per cycle may be expressed as

$$I_L(p)=\left(\frac{N_s}{\pi R_L}\frac{AI_M'-E_c'}{1+AB}\int_0^{\theta(p)}d\theta\right)\text{(before saturation, equation 14)}+\left(0\int_{\theta(p)}^{\pi}d\theta\right)\text{(after saturation)} \qquad (26)$$

$$I_L(p)=\frac{N_s}{\pi R_L}\frac{AI_M'-E_c'}{1+AB}\theta(p) \qquad (27)$$

$$I_L(p+1)=\frac{N_s}{\pi R_L}\frac{AI_M'-E_c'}{1+AB}\theta(p+1) \qquad (28)$$

Substituting the values for $\theta(p)$ and $\theta(p+1)$ into equation 23 yields

$$\frac{R_L}{N_s}AI_L(p+1)-\frac{R_L}{N_s}\theta(p)=E_c'$$

$$I_L(p+1)-\frac{1}{A}I_L(p)=\frac{N_sE_c}{N_cR_LA} \qquad (29)$$

The difference equation for the output current.

STEADY-STATE PERFORMANCE

Under steady-state conditions $I(p+1)=I_{(p)}$

$$I_L(\infty)=\frac{N_cN_sR_s}{R_cR_L}E_c \qquad (30)$$

$$=\frac{N_cN_sR_s}{R_L}I_c$$

$$E_L(\infty)=N_cN_sR_sI_c \text{ as } E_L=R_LI_L \qquad (31)$$

It is seen that the steady-state average load voltage per cycle is independent of both I_M and R_L and depends only upon E_c or I_c. It may further be seen that the performance of the transactor will depend upon the existence of a constant and finite value of eddy-current resistance R_e.

DYNAMIC PERFORMANCE

The complete solution of the difference equation 29 is

$$\lrcorner\!\ulcorner I_L(p)=\left(I_L(0)-\frac{N_cN_sR_e}{R_cR_L}E_c\right)\times \lrcorner\!\ulcorner\left(\frac{1}{A}\right)^p+\frac{N_cN_sR_eE_c}{R_cR_L} \qquad (32)$$

The time constant of the system may be determined from the variable part of the solution.

$\left(\frac{1}{A}\right)=e^{-\alpha\frac{1}{2f}}$ since the duration of each interval is $\frac{1}{2f}$ and $t=\frac{p}{2f}$

The system time constant

$$\tau=\frac{1}{\alpha}=\frac{1}{2f\log(A)}$$

$$=\frac{1}{2f\log\dfrac{N_c^2R_e+R_c}{N_c^2R_e}}\cong\frac{N_c^2R_e}{2fR_c} \qquad (33)$$

It is seen that the time constant of the system may be reduced by decreasing the eddy-current resistance R_e. However, from equation 30, it may be further seen that the current gain also varied directly with R_e.

If power gain k_p is defined as

$$k_p=\frac{I_L^2R_L}{I_c^2R_c}k_f^2$$

where k_f is the form factor of i_L. Then

$$k_p=\frac{N_c^2N_s^2R_e^2}{R_LR_c} \qquad (34)$$

From equations 30, 33, and 34 the dynamic power gain D_p becomes, if

$$D_p=\frac{k_p}{\tau}$$

$$D_p=2f\frac{N_s^2}{R_L}\times R_e\times k_f^2 \qquad (35)$$

If D_p can be considered as a figure of merit, it becomes apparent that the performance of the transactor will be materially improved by using a high-frequency carrier and a high-resistivity core material such as a ferrite.

CORRELATION OF EXPERIMENTAL FACT WITH THEORETICAL FANCY

The theoretical waveshapes of the important voltages, currents and fluxes are drawn in Fig. 10. Starting at the top of the page with the sinusoidal line voltage, it is followed by the square wave of the a-c line current generated by the limiter. The phase angle of i_{ac} lags e_{ac}. However, as the firing angle $\theta(p)$ of the load current i_L is shifted back toward π, the phase difference between e_{ac} and i_{ac} is reduced. This is the result of the load's absorbing more energy and causing the constant current source effectively to supply a larger resistance. The voltage across the limiter is the difference between e_{ac} and N_p/N_se_L. The behavior of the control current i_{c1} is governed by equations 4(A) and 15. The gating portions of e_1 and e_2 are shown positive while the reset voltages are negative. Their magnitudes are given by equations 4, 12, and 13. The core fluxes Φ_1, and Φ_2 are the integrals of e_1 and e_2.

Fig. 11 gives a series of oscillographs of the voltages and currents whose theoretical behavior is depicted in Fig. 10. The true waveforms offer reasonably close agreement with the derived waveshapes.

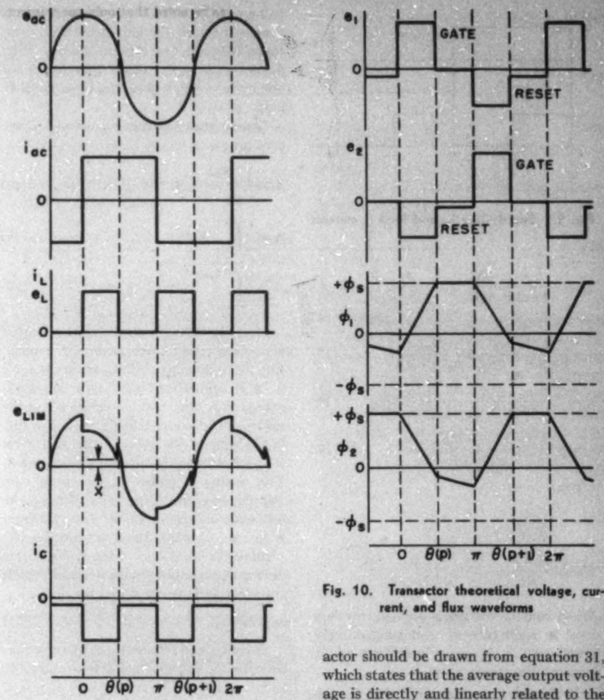

Fig. 10. Transactor theoretical voltage, current, and flux waveforms

The conclusions regarding the steady-state theoretical performance of the transactor should be drawn from equation 31, which states that the average output voltage is directly and linearly related to the average control voltage. It is further implied that within its design range this linear relation between E_L and E_c is completely independent of variations in e_{ac}, I_{lim}, R_L, and supply frequency.

A glance at Fig. 12 immediately shows that the projection of I_L versus I_c does not go to zero when $I_c=0$. Instead, the projection of I_L versus I_c gives a substantial finite value of I_c for $I_L=0$. Since it is known that the static hysteresis loop does in reality have a finite width, this result is not too surprising. It will be treated in a later section when the static **B-H** loop is modified for a finite separation of the ascending and descending legs.

A judicious or perhaps a fortunate choice of simplifying assumptions will often allow the principal experimental results to offer a reasonable resemblance to those predicted theoretically. The choice of **B-H** characteristics has been fortunate in that the test data show excellent correlation of the first-order effects. Fig. 12 has the predicted linear relation between control and load current with the noted offset. Table I lists the output current for three values of con-

trol current with the load resistance and I_{lim} held constant. For each value of I_c, the a-c line voltage was varied 300% to 500%. This covered a range from its maximum allowable value of 90 volts down to a minimum which gave zero residual voltage drop across the limiter. Table II offers the same type of information except that the line voltage is held constant and the effect of a 500% variation of the limiter current is presented. Table III shows the effects upon the output voltage of a load resistance variation of from 25 ohms to infinity. The readings here have been taken for initial open-circuit outputs of 15 and 20 volts. The effects of different values of R_c are also given.

Although the first-order experimental performance agrees quite well with that predicted by theory, closer examination reveals the usual second-order flies in our theoretical ointment. In Table III for R_L under 250 ohms when R_c is greater than 10,000 ohms, the output voltage is found actually to increase with decreasing load resistance. Even Table II with $R_c = 10K$ shows an increasing output current over part of the range of decreasing I_{lim}.

Since the deviation from predicted performance appeared to be a function of R_c (and consequently of E_c) another check was made of I_L versus I_{lim} with $R_c = 13K$, see Fig. 13. Here it was found that the load current would "run away" with decreasing I_{lim}. Further consideration of Fig. 7(A) gave the clue to the reason for this behavior when it became clear that with saturation of the gating core, a large value of e_c would unblock the nonconducting primary rectifier, in this case S_1 during mode I operation. To explain this unexpected variation of I_L with I_{lim}, it is necessary to consider mode I primary rectifier unblocking and consequently the resistance of the primary winding R_p. Referring to the circuit schematic, Fig. 5, switches S_x were opened, inserting the resistance R_p into the transactor primary circuit.

Transactor Performance with Rectifier Unblocking

The original assumptions included the statement that e_c is considered small, and therefore that rectifier S_1 is blocked during the saturated interval of core II. Further study indicates that this statement is true only if $R_p \neq 0$ and if the voltage $I_{ac}R_p$ (N_c/N_p) is greater than $N_c e_0$ or from equation 4.

$$\frac{N_c i_{ac} R_p}{N_p} \geq N_c e_0 = e_c/A = \frac{e_c N_c^2 R_s}{N_c^2 R_s + R_c} \qquad (36)$$

Since, for a given output e_c varies with R_s and R_c, the conditions of equation 36 can be readily upset by increasing R_c or decreasing R_s (common and often desirable variations in the system parameters). The system's behavior must therefore be re-examined during the saturation interval, i.e., second part of the reset interval.

e_{ac} = 70 volts; I_{lim} = 0.30 ampere.

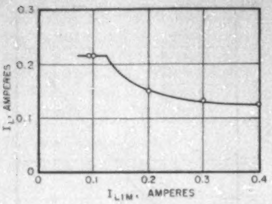

Fig. 13. Plot of load current I_L, versus limiter current I_{lim}

$R_L = 100$ ohms
$R_e = 13$K ohms
$R_p \to 0$ ohms
$E_{AC} = 70$ volts

Assuming that the conditions of equation 36 are not satisfied, Fig. 7(A) must be redrawn; see Fig. 14, with rectifier S_1 unblocked.

Writing the system equations yields

$$e_c - N_c e_0 = i_c R_c \qquad (37)$$

$$N_c i_c - i_e - N_p i_1 = 0 \qquad (38)$$

$$e_0 = i_e R_e \qquad (39)$$

$$e_0 = \frac{i_{ac} R_p + 2 i_1 R_p}{N_p} = \frac{(i_{ac} + 2 i_1) R_p}{N_p} \qquad (40)$$

Solving the four simultaneous equations for the reset voltage e_0 and the control current i_c during the interval yields

$$e_0 = D N_p i_{ac} + 2D \frac{N_c}{R_c} e_c \qquad (41)$$

where

$$D = \frac{1}{2\frac{N_c^2}{R_c} + \frac{2}{R_e} + \frac{N_p^2}{R_p}}$$

$$i_c = \frac{1 - 2DN_c^2}{R_c} e_c - D N_c N_p i_{ac} \qquad (42)$$

Note: $D \to 0$ as $R_p \to 0$

It may be noted in passing that i_c cannot reverse direction and become negative since rectifier S_1 would block, and conditional equation 36 would apply.

Modifying equation 21 with the new value of e_0 (equation 41) yields

$$\frac{B\frac{E_c}{N_c} + R_c N_p I_M}{1+AB} \int_0^{\theta(p)} d\theta + \left(\frac{D}{R_e} N_p R_e I_M + 2D \frac{N_c^2}{R_c} \frac{E_c}{N_c}\right) \int_{\theta(p)}^{\pi} d\theta = \frac{-\frac{E_c}{N_c} + A R_e N_p I_M}{1+AB} \int_0^{\theta(p+1)} d\theta \qquad (43)$$

Letting $E_c/N_c = E_c'$ and $R_e N_p I_M = I_M'$ and integrating, yields the following

$$\frac{BE_c' + I_M'}{1+AB}\theta(p) + \left(\frac{D}{R_e} I_M' + 2D \frac{N_c^2}{R_e} E_c'\right) \times (\pi - \theta(p)) = \frac{AI_M' - E_c'}{1+AB} \theta(p+1)$$

$$(AI_M' - E_c')\theta(p+1) - \left[BE_c' + I_M' - (1+AB)\left(\frac{D}{R_e} I_M' + 2D \frac{N_c^2}{R_c} E_c'\right)\right] \times \theta(p) = (1+AB)\pi\left(\frac{D}{R_e} I_M' + 2D \frac{N_c^2}{R_e} E_c'\right) \qquad (44)$$

Substituting equations 27 and 28 for $\theta(P)$ and $\theta(p+1)$ into equation 44 yields the difference equation for the output load current

$$I_L(p+1) - \frac{BE_c' + I_M' - (1+AB) \times \left(\frac{D}{R_e} I_M' + 2D \frac{N_c^2}{R_c} E_c'\right)}{AI_M' - E_c'} I_L(p) = \frac{N_s}{R_L}\left(\frac{D}{R_e} I_M' + 2D \frac{N_c^2}{R_c} E_c'\right) \qquad (45)$$

Steady state occurs when $I_L(p+1) = I_L(P)$

$$I_L(\infty) = \frac{\frac{DN_s}{R_L}\left(\frac{I_M'}{R_e} + \frac{2N_c^2}{R_c} E_c'\right)(AI_M' - E_c')}{\left(A - 1 + (1+AB)\frac{D}{R_e}\right) I_M' - \left(1 + B - (1+AB) 2D \frac{N_c^2}{R_c}\right) E_c'} \qquad (46)$$

For small values of R_p, and consequently D, equation 46 becomes

$$I_L(\infty) = \frac{\frac{DN_s}{R_L}(AI_M' - E_c')}{(A-1)I_M' - (1+B)E_c'} \times \left(\frac{I_M'}{R_e} + \frac{2N_c^2}{R_c} E_c'\right) \qquad (47)$$

Table IV. Effect of Limiter Current I_{lim} Upon Load Current I_L

0.20	25	0.200	20	1.5
0.4	25	0.500	20	1.5
0.11	100	0.200	20	2.3
0.22	100	0.500	20	2.3

Resistance $R_p = 10$ ohms (no rectifier unblocking).

Obviously, both the numerator and denominator difference terms will go through zero as I_M' is reduced. However, since A and B are always positive real numbers, it is apparent that the denominator term must always go to zero first and thus cause the behavior plotted in Fig. 13.

Experimental Performance Revisited: No Rectifier Unblocking

The deleterious effects of rectifier unblocking attendant upon low values of R_p have been established. By increasing R_p it is possible to eliminate completely any rectifier unblocking. The transactor should then perform as originally predicted by equation 31. Table IV gives the effect of the variation of I_{lim} upon I_L with $R_p = 10$ ohms for several values of R_L and R_e. It is readily observed that while the output no longer increases with decreased I_{lim}, I_L is unfortunately not independent of the limiter current. Some testing of the system with $x=0$, Fig. 10, (peak value of I_M may be held constant after saturation, but varied with E_{ac} during the gating period) indicates that the dependence upon I_{lim} occurs entirely during the gating interval. After the transactor saturates, the magnitude of I_{lim} has no further effect.

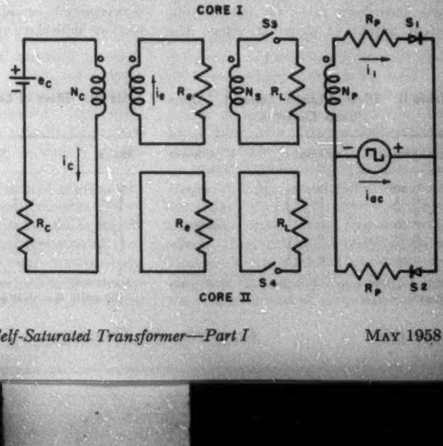

Fig. 14. Equivalent circuit considering R_p with core II saturated

Transactor Performance with Core Hysteresis and Finite Unsaturated Permeability

To reconcile the difference between the behavior experienced with no mode I rectifier unblocking, $R_p \neq 0$, and that predicted by the transactor with a perfect core, it will be necessary to consider a slightly more sophisticated **B-H** characteristic. In Fig. 15(A), static hysteresis exists, and the incremental permeability of the core in the unsaturated state is no longer infinite. The saturated permeability is still taken equal to zero.

Introduction of a finite, constant incremental permeability into the unsaturated conditions will cause the equivalent circuits to show N_p of both core I and core II shunted by a linear magnetizing inductance L_p. To reduce somewhat the complexity of the system and at the same time to highlight the effects of the finite permeability of the core, assume a static **B-H** characteristic, as given in Fig. 15(B). The **B-H** loop of Fig. 7(A) exhibits a finite permeability during the reset half-cycle and an infinite permeability during the setting half-cycle. Although the **B-H** characteristic chosen will never be found in practice, it should serve for the model because during the setting half-cycle, the magnetizing inductance of the gating core will appear across the current source and will not affect the number of volt seconds transformed by the core to the load. For further simplification, R_c shall be assumed to be infinite.

Based upon the **B-H** curve of Fig. 15(B), the setting core will appear as a perfect transformer while the resetting core will have a finite inductance L_p, in parallel with N_p, see Fig. 16. The rectifiers of the resetting core are assumed blocked.

Writing the system equations and taking the Laplace transform, yields

$$e_1(s) - \frac{i_{L_1}(s)R_L}{N_s} = 0 \tag{48}$$

$$e_2(s) - \frac{i_{p2}(s)L_p s}{N_p} + \frac{i_{p2}(0)L_p}{N_p} = 0 \tag{49}$$

$$N_c e_1(s) - N_c e_2(s) + e_c(s) - i_c(s)R_c = 0 \tag{50}$$

$$N_s i_{L_1}(s) - N_p i_{ac}(s) + N_c i_L(s) = 0 \tag{51}$$

$$-N_p i_{p2}(s) + N_c i_c(s) = 0 \tag{52}$$

Considering only the third term of equation 49, leads to the conclusion that

$$\frac{i_{p2}(0)L_P}{N_p} = 0 \tag{53}$$

because, during the latter part of the previous half-cycle when core II was saturated, L_{p2} vanished and therefore $i_{p2}(0) = 0$ at the beginning of the gating cycle.

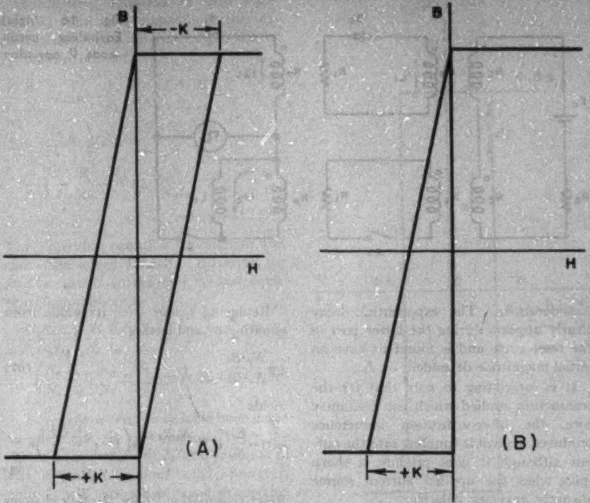

Fig. 15. B-H characteristics with hysteresis and finite unsaturated permeability

Solving the set of simultaneous equations yields

$$\left[\frac{N_s^2}{R_L} + \left(\frac{N_s^2}{R_L}\,\frac{R_c}{N_c^2} + 1\right)\frac{N_p^2}{L_p s}\right] e_2(s) = N_p I_{ac}(s) + \frac{N_s^2}{R_L N_c}\, e_c(s) \tag{54}$$

$$e_1(s) = -\frac{e_c}{N_c} + \left[1 + \frac{R_c}{N_c^2}\,\frac{N_p^2}{L_p s}\right] e_2(s) \tag{55}$$

$$i_{L_1}(s) = \frac{N_s e_1(s)}{R_L} \tag{56}$$

$$i_{p2}(s) = \frac{N_p}{L_p s}\, e_2(s) \tag{57}$$

Let

$$a = \frac{N_s^2}{R_L}$$

$$b = \left(\frac{N_s^2}{R_L}\,\frac{R_c}{N_c^2} + 1\right)\frac{N_p^2}{L_p}$$

$$\alpha = \frac{N_p I_M}{a} + \frac{E_c}{N_c} \tag{58}$$

and take the inverse transform of equations 54, 55, 56, and 57, remembering that

$$e_c(s) = \frac{E_c}{s} \text{ and } I_{ac}(s) = \frac{I_M}{s}$$

Then

$$e_2(t) = \alpha \epsilon^{-\frac{b}{a}t} \tag{59}$$

$$e_1(t) = -\frac{E_c}{N_c} + \frac{\dfrac{R_L}{N_s^2}}{R_c/N_s^2 + R_L/N_s^2}\,\alpha\epsilon^{-\frac{b}{a}t} + \frac{\dfrac{R_c}{N_c^2}}{R_c/N_c^2 + R_L/N_s^2}\,\alpha \tag{60}$$

$$i_{L_1}(t) = \frac{N_s}{R_L}\left(-\frac{E_c}{N_c} + \frac{R_L/N_s^2}{\dfrac{R_c}{N_s^2} + \dfrac{R_L}{N_s^2}}\,\alpha\epsilon^{-\frac{b}{a}t} + \frac{R_c/N_c^2}{\dfrac{R_c}{N_c^2} + \dfrac{R_L}{N_s^2}}\,\alpha\right) \tag{61}$$

$$i_{p2}(t) = \frac{a\alpha}{b}\left(1 - \epsilon^{-\frac{b}{a}t}\right)$$

$$i_{p2}(\theta_p) = \frac{a\alpha}{b}\left(1 - \epsilon^{-\frac{b}{a}\,\frac{\theta(p)}{\omega}}\right) \tag{62}$$

When $t = \theta(p)/\omega$ core I saturates and only E_c is available to continue to reset core II during the remainder of the half cycle; see Fig. 17(A) and (B).

From the reduced equivalent circuit, Fig. 17(B), it may be seen that for the second portion of the reset cycle, the voltage e_0 across core II will exponentially decay toward zero as i_c approaches its terminal value E_c/R_c. This conclusion is borne out experimentally when the voltage across winding N_c of the transactors is examined; see Fig. 18, which further justifies the choice of **B-H** characteristics and the inclusion of L_p in the system

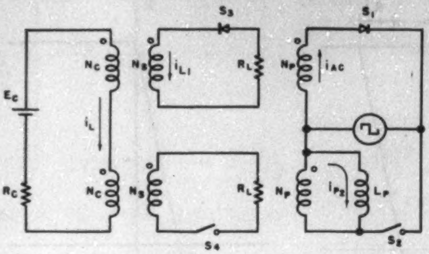

Fig. 16 (right). Equivalent circuit, mode II operation

considerations. The exponential decay clearly appears during the latter part of the reset cycle and is found to have an initial magnitude dependent on I_{lim}.

It is interesting to note that for the transactors studied which use Deltamax core, the after-saturation inductance produced negligible coupling into the output although it does produce a sharp spike when the applied current source abruptly reverses polarity.

Writing the transformed loop voltage and current equations for Fig. 17(A) with $t=0+$ at the instant-when the firing angle equals $\theta(p)$, yields

$$e_c(s)-N_c e_0(s)-i_c(s)R_c=0 \tag{63}$$

$$N_c i_c(s)-N_p i_{p_2}(s)=0 \tag{64}$$

$$e_0(s)-\frac{L_p s i_{p_2}(s)}{N_p}+\frac{L_p i_{p_1}\theta(p)}{N_p}=0 \tag{65}$$

Solving these simultaneous equations yields

$$e_0(s)=\frac{N_c L_p s}{N_c^2 L_p s+N_p^2 R_c}\,e_s(s)-\frac{N_p R_c L_p}{N_c L_p s+N_p^2 R_e}\,i_{p_1}(\theta_p) \tag{66}$$

Taking the inverse Laplace yields

$$e_0(t)=E_c/N_c\epsilon^{-\frac{N_p^2R_c}{N_c^2L_p}t}-\frac{N_pR_c}{N_c^2}i_{p_2}(\theta_p)\epsilon^{-\frac{N_p^2R_c}{N_c^2L_p}t}$$

Replacing $i_{p_1}(\theta p)$ with its value from equation 62 and letting

$$g=\frac{N_p^2R_c}{N_c^2L_p} \tag{67}$$

yields

$$e_0(t)=\frac{E_c}{N_c}\,\epsilon^{-gt}\,\frac{N_pR_c}{N_c^2}\,\frac{a}{b}\,\alpha\left(1-\epsilon^{-\frac{b}{a}\,\frac{\theta(p)}{\omega}}\right)\epsilon^{-gt} \tag{68}$$

Refer to equation 21 for the flux changes during one cycle:

$$\Delta_2+\Delta_0=\Delta_1 \tag{21}$$

Then

$$\frac{1}{\pi/\omega}\int_0^{\frac{\theta(p)}{\omega}}e_2dt+\frac{1}{\pi/\omega}\int_{\theta(p)/\omega}^{\pi/\omega}e_0dt=\frac{1}{\pi/\omega}\int_0^{\frac{\theta(p+1)}{\omega}}e_1dt \tag{21A}$$

Since, from equation 56, the output current $i_{L_1}=N_se_1/R_L$, the average value $I_{L_1}(p)$ of the output current during the pth half-cycle, may be obtained by integrating i_{L_1} over the half-cycle and dividing by π/ω.

$$I_L(p)=\frac{\omega}{\pi}\,\frac{N_s}{R_L}\int_0^{\frac{\theta(p)}{\omega}}e_1(t)dt \tag{69}$$

Multiplying both sides of equation 21(A) by N_s/R_L would cause the right side to become $I_L(p)$. However, the labor involved will be slightly reduced if, before making the substitution, $e_2(t)$ is rewritten in terms of $e_1(t)$. From equation 59 take $\alpha\epsilon^{-b/at}=e_2(t)$ and substitute directly for the like quantity in equation 60 to obtain

$$e_1(t)=\frac{\frac{R_L}{N_s^2}}{\frac{R_c}{N_c^2}+\frac{R_L}{N_s^2}}\,e_2(t)+\frac{\frac{R_c}{N_c^2}}{\frac{R_c}{N_c^2}+\frac{R_L}{N_s^2}}\,\alpha-\frac{E_c}{N_c}$$

Then

$$e_2(t)=\frac{\frac{R_c}{N_c^2}+\frac{R_L}{N_s^2}}{\frac{R_L}{N_s^2}}\,e_1(t)-\frac{R_c}{N_c^2}\,a\alpha+\frac{\frac{R_c}{N_c^2}+\frac{R_L}{N_s^2}}{\frac{R_L}{N_s^2}}\,\frac{E_c}{N_c} \tag{70}$$

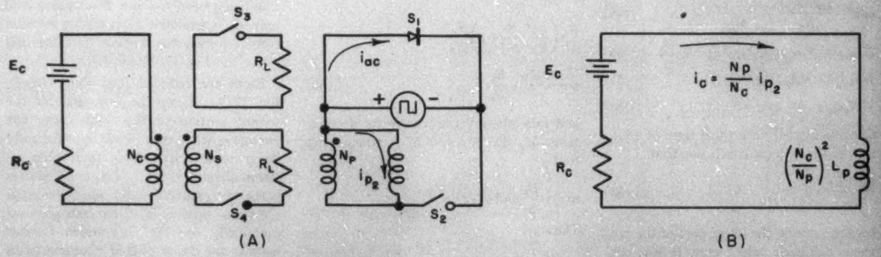
The next step is to multiply equation 21(A) by N_s/R_L and substitute in equations 70, 68, and 69, which will result in a difference equation in the dependent variable $I_L(p)$ and $\theta(p)$.

$$\frac{bL_p}{N_p^2}I_L(p)+\frac{N_s}{\pi R_L}\left(\frac{E_c}{N_c}-\frac{R_c}{N_c^2}N_pI_M\right)\theta(p)-\frac{\omega}{\pi}\,\frac{N_s}{R_{L\theta}}\left[\frac{E_c}{N_c}-\frac{N_pR_c}{N_c^2}\,\frac{a}{b}\,\alpha\left(1-\epsilon^{-\frac{b}{a}\,\frac{\theta(p)}{\omega}}\right)\right]\times\left(e^{-g\frac{\pi}{\omega}}-\epsilon^{-g\frac{\theta(p)}{\omega}}\right)=I_L(p+1) \tag{71}$$

To obtain a second equation in $I_L(p)$ and $\theta(p)$ the integration of equation 69 is performed after replacing $e_1(t)$ with its value from equation 60:

$$I_L(p)=\frac{\omega}{\pi}\,\frac{N_s}{R_L}\left(-\frac{E_c}{N_c}+\frac{R_c/N_c^2}{\frac{R_c}{N_c^2}+R_L/N_s^2}\,\alpha\right)\times\frac{\theta(p)}{\omega}-\frac{\omega}{\pi}\,\frac{N_s}{R_L}\,\frac{a}{b}\,\alpha\left(\frac{R_L/N_s^2}{R_c/N_c^2+R_L/N_s^2}\right)\times\left(\epsilon^{-\frac{b}{a}\,\frac{\theta(p)}{\omega}}-1\right) \tag{72}$$

Equations 71 and 72, containing both



(A)

(B)

Fig. 17. A—Equivalent circuit, mode I operation. B—Reduced equivalent circuit

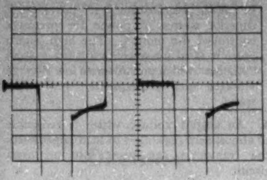


Fig. 18. Oscillograph of transactor reset voltage-expanded scale

first-order and exponential terms involving $\theta(p)$, are not readily solved directly. However, if the exponentials can justifiably be replaced by the first two terms of their expansions, the equations are readily reduced. The smaller the exponents of the exponential become, the more nearly the first two terms of the expansion approach the original function. The exponents under consideration are:

$$\frac{b}{a}\frac{\theta(p)}{\omega}=\frac{N_p^2}{L_p}\left(\frac{R_c}{N_c^2}+\frac{R_L}{N_s^2}\right)\frac{\theta(p)}{\omega}$$

and

$$g\frac{\theta(p)}{\omega}=\frac{N_p^2}{L_p}\frac{R_c}{N_c^2}\frac{\theta(p)}{\omega}$$

Using Arnold Engineering Company's published data for the slope of the Deltamax static **B**-**H** curve, the L_p of the experimental transactor is computed to be 25 henrys. For a $\theta(p)=\pi/2$, an $R_c \cong 1{,}800$ ohms will give an exponent in the vicinity of 0.1. For this range of exponents the exact value of the exponential differs from the value computed from the first two terms of its expansion by less than 0.5%.

Expanding the exponential of equation 72

$$\epsilon^{-\frac{b}{a}\frac{\theta(p)}{\omega}}=1-\frac{b}{a}\frac{\theta(p)}{\omega} \tag{73}$$

Substituting equation 73 into 72 yields

$$I_L(p)\cong\frac{N_s}{\pi R_L}\left(-\frac{E_c}{N_c}+\frac{R_c/N_c^2}{R_c/N_c^2+R_L/N_s^2}\alpha\right)\times \theta(p)+\frac{N_s}{\pi R_L}\frac{R_L/N_s^2}{R_c/N_c^2+R_L/N_s^2}\alpha\theta(p)$$

which reduces to

$$I_L(p)\cong\frac{N_p}{\pi N_s}I_M\theta(p)$$

and (74)

$$\theta(p)=\frac{\pi N_s}{N_pI_M}I_L(p)$$

Substituting equation 74 into equation 71 and also expanding the exponentials gives a difference equation for I_L, the load current.

$$\frac{N_s}{R_L}\frac{E_c}{N_c}+I_L(p)-\frac{N_s}{R_L}\frac{R_c}{N_c^2}\frac{\pi}{\omega}\left(\frac{N_s}{N_c}\frac{E_c}{I_M}+\frac{N_p}{N_s}R_L\right)I_L(p)+\frac{N_s^2}{R_L}\frac{R_c}{N_c^2}\frac{\pi}{\omega}\times\left(\frac{N_s}{N_c}\frac{E_c}{I_M}+\frac{N_p}{N_c}R_L\right)\frac{I_L^2(p)}{N_pI_M}=I_L(p+1) \tag{75}$$

This difference equation is nonlinear and cannot be solved directly. However, for steady state, $I_L(p)=I_L(p+1)$, and equation 75 simplifies to

$$\frac{N_sR_c}{2fN_cN_pI_M}\left(\frac{N_s}{N_c}\frac{E_c}{I_M}+\frac{N_p}{N_s}R_L\right)I_L^2(p)-\frac{R_c}{2fN_c}\times\left(\frac{N_s}{N_c}\frac{E_c}{I_M}+\frac{N_p}{N_s}R_L\right)I_L(p)+E_c=0 \tag{76}$$

Too many assumptions have been made to allow the use of equation 76 for the direct computation of I_L as a function of I_M. Equation 76 does prove, however, that I_L will increase in some proportion (but not quite in direct proportion) with increasing I_M.

When R_p is very small and R_c is large, the primary rectifier will unblock and the output will decrease as I_{1lm} is increased. On the other hand, with no rectifier unblocking, the opposite effect is true. By adjusting R_p and R_c it is possible to limit the output variation to a few per cent even with a 100% variation of I_{1lm}. It should be further noted that in practice it is usually a relatively simple matter to regulate I_{1lm} closely.

Transactor Performance with Core Hysteresis and Infinite Unsaturated Permeability

Equation 31, which was derived assuming a perfect **B**-**H** characteristic, predicts that the output load current I_L will be zero when $E_c=0$ and will increase linearly with E_c. Examining a typical variation of I_L versus I_c, Fig. 12, it is seen that the output remains constant at a low value until E_c reaches a rather substantial figure, and only then does I_L vary with I_c. The answer to this discrepancy lies again in the **B**-**H** loop assumptions. If it is assumed now that the core material possesses a static hysteresis characteristic with vertical sides, Fig. 19, the experimental behavior can be readily explained. K, the static coercive magnetomotive forces in ampere turns equals H_cl_1.

The equivalent circuit before saturation will be as shown in Fig. 7(B). The circuit equations will be the same as previously written except for the factor K in the sum of the ampere-turn equations.

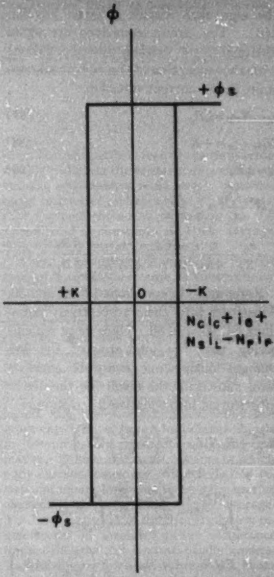

Fig. 19. B-H characteristic with hysteresis and infinite unsaturated permeability

$$e_1=i_{e1}R_e \tag{77}$$

$$e_1=\frac{i_{L1}R_L}{N_s} \tag{78}$$

$$e_2=i_{e2}R_e \tag{79}$$

$$e_c+N_ce_1-N_ce_2=i_cR_c \tag{80}$$

$$N_ci_c-i_{e2}=+K \tag{81}$$

$$N_ci_c+i_{e1}+N_si_{L1}-N_pi_{ac}=-K \tag{82}$$

Solving the foregoing equations yields

$$e_1=\frac{K(R_c/N_c^2-2AR_e)+AN_pR_ei_{ac}-e_c/N_c}{1+AB} \tag{83}$$

$$e_2=\frac{N_pR_ei_{ac}+Be_c/N_c-\pi\left(B\frac{R_c}{N_c^2}+2R_e\right)}{1+AB} \tag{84}$$

$$i_{L1}=\frac{1}{1+AB}\frac{N_s}{R_L}\left[K\left(\frac{R_c}{N_c^2}-2AR_e\right)+AN_pR_ei_{ac}+\frac{e_c}{N_c}\right] \tag{85}$$

$$i_c=\frac{K}{N_c}+\frac{e_2}{N_cR_e} \tag{86}$$

After saturation of the setting core,

the equivalent circuit is given by Fig. 7(A). The circuit equations are again identical to the original system relations with the exception of the additional constant in the current equation.

$$e_c - N_c e_0 = i_c R_c \quad (87)$$

$$N_c i_c - i_e = +K \quad (88)$$

$$e_0 = i_e R_e \quad (89)$$

$$e_0 = \frac{e_c/N_c}{A} - \frac{K}{A}\frac{R_c}{N_c^2} \quad (90)$$

$$i_c = \frac{e_c}{R_c} - \frac{e_c}{AR_c} + \frac{KR_c}{AN_c} = \frac{e_c}{AN_c^2R_e} + \frac{KR_e}{AN_c} \quad (91)$$

Refer again to equations 18, 19, and 20. Substitute into them respectively equations 84, 90, and 83. Once more remembering that the total sum of the flux changes during one complete cycle is zero, substitute the results of the above substitution into equation 21 to obtain:

$$\frac{B\dfrac{E_c}{N_c} + R_eN_pI_M - K\left(B\dfrac{R_c}{N_c^2} + 2R_e\right)}{1+AB} \times \int_0^{\theta(p)} d\theta + \frac{\dfrac{E_c}{N_c} - K\dfrac{R_c}{N_c^2}}{A}\int_{\theta(p)}^{\pi} d\theta$$

$$= -\frac{E_c/N_c + AR_eN_pI_M + K\left(\dfrac{R_c}{N_c^2} - 2AR_e\right)}{1+AB} \int_0^{\theta(p+1)} d\theta \quad (92)$$

Integrating, let $E_c/N_c = E_c'$ and $R_eN_pI_M = I_M'$ again to obtain a difference equation relating the p and $p+1$ cycles.

$$\left(A^2I_M' - AE_c' - 2A^2KR_e + AK\frac{R_c}{N_c^2}\right)\theta(p+1) - \left(AI_M' - E_c' - 2AKR_e + K\frac{R_c}{N_c^2}\right)\theta(p) = \pi(1+AB)\left(E_c' - K\frac{R_c}{N_c^2}\right) \quad (93)$$

Integrating equation 85 to obtain the average load current in a given half cycle:

$$I_L(p) = \frac{1}{1+AB}\frac{N_s}{R_L}\left[K\left(\frac{R_c}{N_c^2} - 2AR_e\right) + AI_M' - E_c'\right]\frac{1}{\pi}\int_0^{\theta(p)} d\theta$$

$$\theta(p) = \frac{\pi(1+AB)R_L}{N_s} \times \frac{I_L(p)}{\left[AI_M' - E_c' + K\left(\dfrac{R_c}{N_c^2} - 2AR_e\right)\right]} \quad (94)$$

$$\theta(p+1) = \frac{\pi(1+AB)R_L}{N_s} \times \frac{I_L(p+1)}{\left[AI_M' - E_c' + K\left(\dfrac{R_c}{N_c^2} - 2AR_e\right)\right]} \quad (95)$$

Substituting equations 94 and 95 into 93 obtains the difference equation for the load current:

$$I_L(p+1) - \frac{1}{A}I_L(p) = \frac{N_s}{AR_L}\left(\frac{E_c}{N_c} - K\frac{R_c}{N_c^2}\right) \quad (96)$$

This equation has exactly the same form as that of equation 29 which described the performance of the system with a perfect **B-H** characteristic. The dynamic performance of the system will therefore remain unchanged. The time constant, power gain, and figure of merit are described by equations 33, 34, and 35. However, since the right-hand side of the equation is a function of E_c minus a constant, the steady-state relation of I_L versus E_c must be modified.

$$I_L(\infty) = I_L(\infty+1)$$

$$I_L(\infty) = \frac{N_c^2N_sR_e}{R_cR_L}\left(\frac{E_c}{N_c} - K\frac{R_c}{N_c^2}\right) = \frac{N_sR_e}{R_L}(I_cN_c - K) \quad (97)$$

Equation 97 indicates that the steady-state load current will theoretically go to zero when

$$E_c = \frac{KR_c}{N_c} \text{ or } I_c = \frac{K}{N_c} \quad (98)$$

Consideration of the assumed **B-H** characteristic shows that the output will remain at zero for $E_c < KR_c/N_c$. The net result then of assuming a **B-H** characteristic with finite and constant hysteresis is to give the same steady-state I_L versus I_c characteristic that may be expected from the perfect core, except that all values of I_c have been displaced by the constant amount K/N_c.

Conclusions

The parallel loaded, full-wave magnetic amplifier has been explored. A self-saturated transformer, the transactor, has been developed. The salient features of its experimental behavior have been explained by the use of a series of elementary **B-H** core characteristics.

The transactor offers performance which in several respects is superior to that of the conventional series-loaded magnetic amplifier. The advantages are:

1. Improved transient and steady-state output stability for extreme variations of line, load, and frequency.
2. The quality of being fail-safe: a short circuit on the output will not overload it.
3. A rectangular, pulse-width modulated output wave with the following characteristics:
   a. It is ideal for driving stages of transistor power amplification.
   b. With rectification, it provides a superior source of power for precisely controlled d-c motors. The high, sharp pulse is ideal for overcoming the system "stiction" which prevails with low average voltages and consequently very slow speed.
4. An output voltage which is reducible to almost zero regardless of load impedance; the transactor can work into an open circuit.
5. Magnetic interstage coupling which is conveniently achieved; quiescent current effects are reduced.
6. Use of the half-wave transactor as a building block for new circuits including a full-wave phase-reversible amplifier and a variation of Patten's pulse stretch concept.[9] (These variations of the transactor will be described in Part II.)
7. Convenient temperature compensation: the analysis of the transactor, confirmed experimentally, shows the output to be a direct function of the core eddy-current resistance. Temperature compensation is therefore readily achieved by connecting appropriate temperature compensating resistors across a winding of each core of the transactor.
8. Multiple transactor operation from a single limiter. By proper proportioning of the primary windings a number of transactors may be fed in series from a single limiter without interaction of the outputs.

More exact correlation of the transactor's experimental and theoretical performance will require the use of more sophisticated **B-H** characteristics.[10,11] In addition, further consideration of additional second- or third-order effects such as interwinding capacitance, rectifier leakage, and after-saturation inductance will become necessary. With the use of lower-quality cores possessing less square **B-H** loops, the effects of after-saturation mutual inductance should become particularly noticeable.

◆

Discussion

R. M. Hubbard (Boeing Airplane Company, Seattle, Wash.): The author is to be commended for his analysis of a type of magnetic amplifier circuit connection which has been seriously neglected in the past. The discusser has also been interested in this general type of connection and has found only one earlier reference[1] to the technique described in the paper for coupling the load to a magnetic amplifier. However, it is felt that the author in his analysis has overemphasized the uniqueness of this load coupling technique to the point of beclouding the fact that the transactor is not fundamentally different from the conventional self-saturating circuit. Basically the transactor may be classified as a self-saturating magnetic amplifier in which the conventional load is termed a "limiter" while the true load is transformer-coupled in shunt with the gate winding. The fact that the author has provided a unique type of limiter in the form of a series saturable reactor should not alter this statement. Since it has been this discusser's practice in the past to draw attention to the basic and extensive similarities between different classes of magnetic amplifier circuits by treating them with a single method of analysis,[2,3] he is inclined to believe that the author's conclusions about voltage gain, current gain, dynamic power gain, the effect of eddy-current resistance, etc., are identical to the conclusions one would reach in the treatment of a conventional self-saturating circuit. For example, assuming that the author's use of a linear eddy-current resistance R_e, to account for the finite excitation impedance of the core, is equivalent to the discusser's use of an average nonlinear resistance $\bar{R}$, one finds that transactor equations 31, 33, and 35 are equivalent to equations 5, 15, and 48 respectively, in the discusser's analysis of the simple full-wave self-saturating circuit.[2]

I am inclined to take exception to several of the author's statements relating to the representation of the magnetic core characteristics in terms of equivalent linear elements. First, as has been previously indicated, the conclusion that the transactor output is a direct function of eddy-current resistance R_e is also directly applicable to the simple self-saturating circuit. Therefore, if this fact in reality makes for convenient temperature compensation of the transactor, then the same is true of the conventional circuit and no advantage of one circuit over the other can be claimed on the strength of this point. More important, however, I do not feel that the representation of the equivalent eddy-current resistance as a linear resistance is justifiable in view of physical realities, in spite of the fact that such an assumption is essential to a straightforward analysis in terms of instantaneous values. This point is more clearly seen if one considers a transactor in which the excitation current is sinusoidal. Under such conditions, the flux-current loop would be substantially elliptical rather than rectangular. One is forced to conclude that an equivalent eddy-current resistance must be instantaneously nonlinear. In contrast, the beauty of a half-cycle average type of analysis lies in the fact that even though the eddy-current resistance be instantaneously nonlinear, the average value may be treated as a linear quantity. This is analogous to the fact that even though the functional relationship between the input and the output of a magnetic amplifier is discontinuous, this relationship in terms of half-cycle average values can be substantially linear. Thus, it is felt that the author's conclusion, in the section "Steady-State Performance" to the effect that the performance of the transactor will depend upon the existence of a constant value of eddy-current resistance, is unnecessarily restrictive and should in reality state that the performance is dependent on the existence of a constant half-cycle average value of eddy-current resistance.

Since, in practice, the excitation impedance of a square-loop core is substantially resistive both statically and dynamically, it is felt that the author's neglect of the static loop by considering only the eddy-current resistance does not conflict excessively with physical reality (except in the case of ferrites). However, it is felt that the author's "more sophisticated" **B-H** loop in which the eddy-current resistance is neglected, and the core excitation impedance represented by a linear inductance L_p, is in complete disagreement with physical reality. Even static measurements in which eddy-current losses are truly negligible reveal the square-loop core to be a dissipative element with very little energy storage. The representation of the core excitation requirements in terms of linear inductance implies that the core is substantially lossless. In fact, the author's assumption of a linear magnetizing inductance is incompatible with the corresponding **B-H** characteristic of Fig. 15 which is valid for a 100% lossy element. It is suspected that the exponential-like decay illustrated by Fig. 18 may be more realistically related to a natural rate of change of flux under conditions of constant current drive independent of R_e and thus independent of any L/R time constant. Investigations of this sort have been reported by Huhta[4] and others.

The problem of deriving a satisfactory equivalent circuit for the saturable transformer utilizing square-loop cores is a fascinating one. The work of Kikuchi and of Feth, (see references 8 and 10 respectively

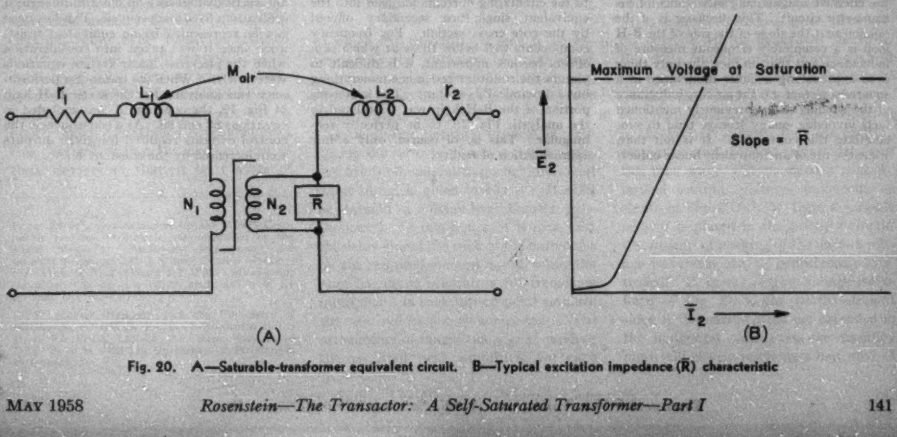

Fig. 20. A—Saturable-transformer equivalent circuit. B—Typical excitation impedance ($\bar{R}$) characteristic

of the paper) has shed considerable light on the dynamics of core operation with reference to certain restrictive operating conditions. However, nothing approaching a general analysis of core behavior which is not restricted by waveforms, impedance levels, etc., has yet appeared. I have found that this problem may be circumvented to a great extent by restricting the discussion to half-cycle average values. As a result, the excitation impedance may be represented as a nonlinear average resistance which is surprisingly independent of the waveforms of current and voltage involved.

An equivalent circuit for the saturable transformer, utilizing a square-loop core, which has been found compatible with a variety of experimental observations is presented in Fig. 20(A). The "ideal" transformer is an ideal saturating transformer which has infinite permeability in the unsaturated region and zero permeability in the saturated region. The linear inductances L_1 and L_2 correspond to the air-core inductances of the N_1 and the N_2 windings respectively, and the resistances r_1 and r_2 correspond to the winding resistances of the N_1 and the N_2 windings respectively. The quantity $\hat{R}$ is the nonlinear, half-cycle average excitation impedance of the N_2 winding. $\hat{R}$ may typically be determined empirically with a simple variable reset, half-wave test circuit. Typically, though $\hat{R}$ is nonlinear, it will be found to be characterized by two substantially linear regions, as illustrated in Fig. 20(B). The first is a low-impedance region corresponding to the threshold characteristic of square-loop cores in which very little flux change occurs. The second region is a high-impedance region encountered when the threshold ampere turns are exceeded. One limitation on this equivalent circuit is imposed by the fact that practical materials do not saturate as sharply as the "ideal" core, with the net result that the average voltage across $\hat{R}$ actually rises slightly as the core is driven into saturation.

It is commonly assumed that the inductance of a winding on a square-loop core has two distinct values: one associated with the high differential permeability corresponding to the slope of the side of the **B-H** loop and the other associated with the low permeability in saturation. The author has used the former value of permeability to calculate the effective magnetizing inductance of his transactor circuit. This discusser is of the opinion that the slope of the side of the **B-H** loop is a completely erroneous measure of inductance and that, in fact, the only thing even approaching a linear inductance in a square-loop reactor is the air-core inductance of the winding. The previously mentioned facts involving energy storage tend to substantiate this contention. It is felt that, while the use of an equivalent linear inductance and resistance may be justifiable in the representation of the excitation impedance of low-remanence transformer cores, a similar attempt to linearize such a distinctly nonlinear element as a square-loop core is doomed to failure.

Allen B. Rosenstein: The author wishes to thank Mr. Hubbard for his thorough review. Mr. Hubbard's own works were valuable sources of information and guidance.

The author agrees that the transactor is one of a family of self-saturating magnetic amplification devices. In each case a large impedance is reflected into the supply circuit during mode II while the control voltage effectively divides itself between the reflected resistances and the series resistance R_c. During mode I, all circuits are coupled. Under these circumstances it is indeed natural to expect the parallel and series loaded amplifiers to possess identical transfer features. However, it should be noted that the use of a resistance limiter would have modified the gain equations of the transactor since the resistance of the limiter would be reflected in parallel with the load. It was not the intention to disguise the true parents of the transactor. It was hoped that the section "Parallel Output" along with Fig. 3 would clearly define the relationship.

The author is not certain whether the differences in the nature of the eddy-current resistance are conceptual, physical, or semantic. It was intended to separate the low-frequency characteristics of the core into its hysteresis and eddy-current components with the eddy currents being restricted to the circulating currents induced into the equivalent single-turn secondary offered by the core cross section. For frequency components well below those at which skin effects become important, it is difficult to picture the resultant resistance as anything but a dynamically constant. The hysteresis portion of the **B-H** loop was postulated in the analysis, Fig. 19, to be perfectly rectangular. This is, of course, only a fair approximation of reality.

An effort was made to determine theoretically and experimentally the mechanism of output voltage variation with change in limiter current. With a core postulated to possess only a constant eddy-current resistance and a rectangular static hysteresis loop, the output is completely independent of the limiter current. Since experimentally the output was found to vary somewhat with limiter current, one is lead to investigate further the possibilities of finite permeability in either the saturated or unsaturated region. A series of experiments was conducted to determine the more likely suspect.

Referring to the limiter voltage e_{lim} in Fig. 10, it may be seen that by biasing the limiter high enough, the limiter voltage will go to zero during the gating interval. This means that the x shown in Fig. 10 will be zero during the entire interval and all of the supply voltage will appear across the output. Under these circumstances, the limiter will not control the current during the gating interval, but will limit the load current only after the transactor has saturated. This means that changes in limiter current will only cause current changes through the aftersaturation inductance. Under these circumstances it was found that substantial changes in limiter current had no effect upon the transactor output. However, if with x still equal to zero, the a-c supply voltage was varied causing a change in the instantaneous magnitude of current flow through the transactor during the gating interval, then the same changes in output would appear as when $x \neq 0$ and the limiter current was varied. From this experiment and the behavior of the transactor reset voltage shown in Fig. 18 it was concluded that the aftersaturation inductance of the experimental transactor was not as important as the finite unsaturated permeability or magnetizing inductance.

The **B-H** characteristics with hysteresis and finite unsaturated permeability of Fig. 15 were assumed to investigate analytically these conclusions. To reduce the labor of the rather cumbersome equations generated by the inclusion of inductance in the equivalent circuits, it was decided not to consider the eddy-current resistance. As the discusser points out, this does not mean that the cores are lossless. However, since the static hysteresis loop has a finite area, it will cause a fixed loss per cycle. This loss need not be represented by an equivalent resistance since it was taken into consideration when the piecewise linear system equations were written. When the transactor performance was analyzed for the static **B-H** loop of Fig. 19, the constant K was included in equations 82 and 88. As a consequence, the control currents required for given outputs were increased by the constant K/N_c.

The Design of Function Generators Using Short-Time Memory Devices and Nonlinear Elements

A. W. REVAY
ASSOCIATE MEMBER AIEE

D. J. FORD
ASSOCIATE MEMBER AIEE

THE ANALOG COMPUTER FIELD is frequently concerned with the generation of periodic nonsinusoidal functions of time. At present this waveform generation is frequently performed with biased diode networks, curve followers, and synchronous switches. The main purpose of this paper is to give the theoretical design and analysis of nonsinusoidal function generators which utilize delay-type or short-time memory devices and certain nonlinear elements in their structure. The different types of function generators to be discussed have the common property that the output waveform may be controlled easily and may be made to approximate various desired shapes to high degrees of accuracy.

This paper is meant to be exploratory, in a theoretical sense only, of a sizable number of different methods of waveform generation using short-time memory devices and certain nonlinear elements. It is hoped at a later date to submit further theoretical work together with the experimental verification and quantitative evaluation of some of these methods.

Throughout this paper the delay-type device will be assumed ideal, i.e., the attenuation along the device will be assumed zero, and the phase shift will be assumed linear throughout the frequency range of interest. The increased use of short-time memory devices, particularly electromagnetic delay lines, has resulted in the development and commercial production of delay devices which closely approximate these ideal conditions over a significant range of frequencies. It is hoped that the continued development of this field will reduce the size and cost of these devices so that at least some of the methods suggested in this paper will find economical application.

Delay-Line Fourier Synthesizer

In all of the work which follows, the delay-type or short-time memory device will be assumed to be an electromagnetic delay line having the "ideal" characteristics over the indicated frequency range.

A large class of continuous periodic waveforms of engineering significance may be analyzed by Fourier series methods. A typical expression for such a waveform is

$$y(t)=C_0+C_1\sin(\omega t-\phi_1)+C_2\sin(2\omega t-\phi_2)+\ldots+C_n\sin(n\omega t-\phi_n)+\ldots \quad (1)$$

where the constants C_0, C_1 ... are obtainable from various integrals of the given function, $y(t)$, and from sine and cosine functions by well-known mathematical methods. Although the series in equation 1 has an infinite number of terms, there exist many important periodic waveforms for which relatively few terms give a close approximation to the given nonsinusoidal waveform. To a high degree of accuracy one of these periodic waveforms may be represented by

$$y(t)=C_0+\sum_{k=1}^{m}C_k\sin(k\omega t-\phi_k) \quad (2)$$

in which the waveform is seen to be expressed by the finite sum of a number of sine waves of different frequencies, different peak amplitudes, and different phase shifts or phase delays.

A delay-line network capable of producing the series of equation 2 when subject to a fundamental-frequency sinusoidal input signal is given in Fig. 1. It shall be termed a "delay-line Fourier synthesizer." In this figure, it is seen that the delay-line shifts each of the harmonics by the required amount ϕ_K/K, while the pure harmonic generators (or frequency multipliers) in each tap-off point produce the required frequency component. The attenuators of magnitude C_K/M produce the required peak amplitude for each frequency component. It is noted that each phase shift required of the delay line in only (ϕ_K/K) rather than ϕ_K itself. In particular cases this might be of considerable advantage in that the total magnitude of phase shift required for the delay line in terms of the fundamental frequency, is 180 degrees maximum, and might be considerably less. The fact that all of the phase shift angles obtainable from the delay line are negative poses no difficulty when it is recognized that, on a steady-state basis, any calculated positive angle ϕ_K may be replaced by $(\phi_K-360$ degrees). This latter angle will be negative since ϕ_K is by definition less than 360 degrees. The substitution of $(\phi_K-360$ degrees) for ϕ_K in the phase shift portion of a component of equation 2 does not alter the resulting steady-state waveshape.

It is noted that the main components of the delay-line Fourier synthesizer of Fig. 1 are the harmonic generators required for each tap-off point along the line. The following three sections describe three different ways in which these harmonic generators might be designed.

MAGNETIC-CORE HARMONIC GENERATOR

The magnetic-core harmonic generator presents a method of controlling a voltage waveshape by means of the nonlinear characteristics of a magnetic core. When several magnetic cores are used in conjunction with a delay line, it is possible to produce a harmonic component as needed for the Fourier synthesizer and indicated in equation 2. The input signal to the magnetic-core harmonic generator is assumed to be a sine wave of the fundamental frequency required in the waveform synthesis.

If a sinusoidal voltage e_g is applied to the input of the circuit shown in Fig. 2(A), and if the primary circuit resistance (R_g+R_1) is assumed to be negligible, the exciting current will be peaked as shown in Fig. 2(B), but the output waveform will be essentially sinusoidal as indicated.[1] On the other hand, if R_g and R_1 are large, or if additional large resistance is inserted in the primary circuit, then the exciting current would become sinusoidal, and the flux wave will produce a sharply peaked output voltage waveform as shown in Fig. 2(C).[2] If, then, a variable resistor is placed in the primary circuit, the amount of peaking of the output voltage waveform can be continuously controlled. If, in the output voltage waveform of Fig. 2(C), the nearly straight sides of the narrow peak are extended to the horizontal time axis, the resulting pulse will closely resemble a half-wave of

sine wave of higher frequency than the fundamental. If the pulse width is defined as the angle measured between the intersections of the extensions of the nearly straight sides of the pulse and the horizontal axis, the pulse width may be varied from 180 degrees to some value 180 degrees $/S$, where S is limited by the hysteresis loop of the iron and the peak input voltage. When S is adjusted to a value 2.00, the two pulses appearing in an output voltage cycle will approximate the positive and negative half-cycles of the second harmonic. In general, for integer values of S, say K, the pulse portions of the output waveform will approximate the half-cycles of the Kth harmonic; see Fig. 3.

A true, relatively pure Kth harmonic sinusoidal waveform may be produced by connecting either K or $2K$ iron cores in delay-line networks as shown in Fig. 4. The second and third harmonics are used as examples in these figures, but the general configurations may be directly extended to other odd and even harmonics. From these figures, it is seen that the iron-core circuits are connected along the delay lines in such a fashion that their input signals are displaced from one another by 180 degrees$/K$, the angles being measured with respect to the fundamental frequency component. By summing the successively displaced pulsed waveforms, the resultant relatively pure harmonic output is produced. The small amplitude sections of the individual core outputs which link the positive to the negative pulses tend to cancel out in the summation used to produce the output signal.

Experimentally, the value of primary resistance needed could be determined by adjusting the variable resistor indicated in the primary circuit until the desired peaking of the waveform is produced. The variable resistor could then be replaced by a fixed resistance element. Because of the small size of the magnetic cores, the physical size of this magnetic-core harmonic generator would be quite small. Because only the fundamental sinusoidal waveform input voltage passes through the delay line, many of these harmonic generators could be connected to the same delay line. If there were sufficient taps on the delay line, or if a mechanism for continuous adjustment of the delay time were available, it would be possible to shift each of these harmonic generators as a complete unit by the proper phase amount ϕ_K, as determined by equation 2.

In cases where the iron-core hysteresis loop limits the number of harmonics obtainable, one of these obtainable harmonics may be connected as the input to an auxiliary delay line. The magnetic-core harmonic generators connected at output taps of the auxiliary delay line will give harmonics of the input harmonic.

The number of harmonics might also be increased by placing a series capacitor in the primary circuit to "tune out" the inductive effects and permit an exact sinusoidal current waveform. However, even without these extra measures, the square-hysteresis-loop magnetic cores commercially available will provide a sufficiently high number of harmonics for most Fourier synthesis applications.

It might seem desirable to utilize the alternate method of using one magnetic core to obtain the desired pulse width and then to shift these pulses by a delay line. The resultant waveform would then be obtained by summing the shifted pulses in the usual manner. Although this might be satisfactory for certain frequency ranges of operation, it is thought that the high harmonic content of the pulses would require a delay line

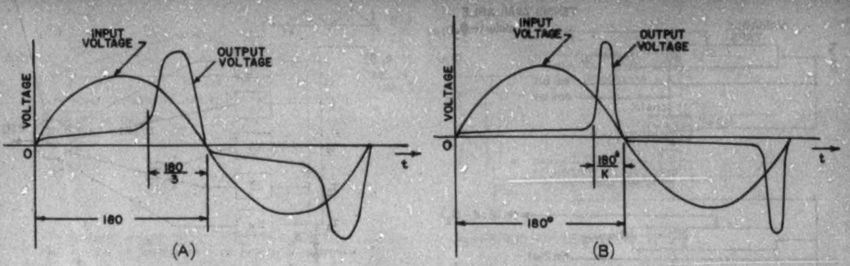

Fig. 3. Output waveform of magnetic-core harmonic generator unit showing peaking: A—to form a portion of third harmonic. B—to form a portion of Kth harmonic

having a relatively much higher cutoff frequency than the network just considered. This system would require either one delay line for each Fourier series component, or a complicated set of filters to receive the respective pulses. The first case would seem to be economically unsound compared to the system discussed because delay lines are much more costly than iron cores. The second method would probably be economically unsound also, since the complicated set of filters could just as easily be used with the original distorted wave. This would eliminate entirely the need for the delay-line mechanism.

Nonlinear-Element Harmonic Generator

A network or device which possesses a specific type of nonlinear volt-ampere characteristic may serve as a harmonic generator. To illustrate, consider a solid-state diode or device whose volt-ampere characteristic is describable by

$$i = Ke^{a} \tag{3}$$

If a pure fundamental-frequency sinusoidal voltage is applied to this device with the loading effects adjusted so that equation 3 gives the dynamic volt-ampere characteristic with *a* equal to two, a second harmonic component of current will be generated as indicated by

$$i = K(E_m \sin \omega t)^2 \tag{4}$$

$$= \frac{KE_m}{2} - \frac{KE_m}{2} \cos 2\omega t \tag{5}$$

The d-c component would have to be balanced out, or blocked by capacitive coupling, or possibly used to form the d-c term in the Fourier series of equation 2.

Fig. 5 (left). Multiplier type of waveform generator

If the a of equation 3 were 3 under dynamic or loaded conditions, a third harmonic component of current could be obtained. The resulting equations would become

$$i=Ke^3=KE_m{}^3\sin^3\omega t \qquad (6)$$

or

$$i=\frac{3}{4}KE_m{}^3\sin\omega t-\frac{1}{4}KE_m{}^3\sin 3\omega t \qquad (7)$$

Filtering could be used to remove the third harmonic component, or possibly a fundamental-frequency component could be added to the wave of equation 7 in such a manner as to cancel the first term on the right side of the equation.

It is possible to cascade combinations of second- and third-harmonic generators in order to obtain harmonic terms of higher order. Performed in this fashion, there exist only certain harmonics which may be obtained, as follows: 1, 2, 3, 4, 6, 8, 9, ... (2^x3^y), where x, y are positive integers, including zero.

Individual nonlinear devices described by equation 3 with a greater than 5 usually do not provide a sizable output signal amplitude. For some devices, the accurate control of the operating point conditions and/or the loading conditions is quite difficult. Generally, the use of silicon carbide varistors appears attractive for this generator.

MULTIPLIER-TYPE HARMONIC GENERATOR

The harmonic components of the finite Fourier series of equation 2 may be produced through the use of a network of delay lines, adders, and multiplication devices. A general form of the network is given in Fig. 5. This network makes use of the trigonometric identity

$$\sin(\alpha+\beta)=\sin\alpha\cos\beta+\cos\alpha\sin\beta \qquad (8)$$

or, in more general form,

$$\sin K\omega t=\sin n\omega t\cos m\omega t+\cos n\omega t\sin m\omega t \qquad (9)$$

where

$n+m=K$ for K odd
$n=m=K/2$ for K even

The network of Fig. 5 may be extended to produce as many harmonics as desired. As indicated in the figure, the cosine function is readily obtainable at the $3\pi/2$ tap, or negatively at the $\pi/2$ tap. The phase angle of the nth harmonic may be varied if a variable delay-line tap is provided at the output. By choosing the proper phase shift and peak amplitude for each harmonic component, a given complex wave may be synthesized through the addition of the harmonic components obtained from this network.

At present, objection might be made to the frequent use of multipliers because in the present state of the art they are both expensive and relatively inaccurate for certain frequency ranges. However, it is believed that the network as described has no other theoretical difficulties. It is hoped that the near future will bring improved multipliers which will make this design more practical.

In the design of an actual network of this type, the possibility of feedback between channels might have to be considered. If the feedback should prove objectionable, certain isolation devices would have to be added to compensate for the parasitic elements causing it.

It would seem that this multiplier-type harmonic generator would find its greatest use in cases where only a small number of harmonics are needed. For a large number of harmonics, the complexity of the network might make its use unwise.

LIMITATIONS OF THE DELAY-LINE FOURIER SYNTHESIZER

The methods of generating nonsinusoidal periodic waveforms described thus far have required that one of the following steps be performed:

1. A Fourier analysis made of the waveform to determine the correct amplitudes and phase angles of the significant harmonics.
2. A trial and error experimental method

of amplitude and phase angle adjustment made, in order to fit the required waveform.

Both methods are usually time-consuming although necessary for the design of the foregoing networks.

The accuracy with which the resultant synthesized waveform approximates the ideal model is determined by the accuracy with which the magnitude and phase of the harmonic components are determined and by the number of harmonic components used to make up the resultant waveform. The number of harmonics required for a given accuracy of approximation is a function of the waveform to be synthesized. In general, greater accuracy is obtained by increasing the number of harmonic components used, but this procedure also increases the cost and the complexity of the generator. In a given case a compromise between cost and accuracy would have to be met. The method of waveform generation described in the next section does not require the time-consuming preliminary work indicated in the foregoing.

Function Generation by Waveform Approximation

A given periodic function of time may be approximated by fitting generated curve segments to various sections of the given curve. The two main classifications of curve fitting or waveform approximation which will be considered here are: 1. straight-line or first-degree approximation, and 2. curved-line or higher-degree approximation. The higher-degree approximation can give the greater accuracy for a given number of segments, if an effective means of controlling the segment curvature is available.

This section will describe several methods using short-time memory devices by which waveforms may be approximated by a straight-line segment method and by a higher-degree polynomial segment method. Both methods have the advantage of flexibility and ease of control.

The Kallman transversal filter network will be used in the proposed waveform generators.[8] A given set of networks will be connected at the delay line taps of the transversal network in order to give the over-all network various transfer characteristics as the input signal proceeds along the delay line.

STRAIGHT-LINE APPROXIMATION METHOD

There are several types of similar transversal networks which may be used under somewhat restrictive conditions for the purpose of function forming, with the use of straight-line segments. One of these, originally suggested by Sze, is given in Fig. 6. It is seen that the output signal $e_0(t)$ of Fig. 6 may be written in terms of the input signal $e_i(t)$ as

$$e_0(t)=K_0e_i(t)+K_1e_i(t-T_1)-K_2e_i(t-T_2)-K_3e_i(t-T_3)+K_4e_i(t-T_4) \quad (10)$$

In the general case, the sign preceding any K_i can be made plus or minus by connection to the proper summing device indicated in the figure.

One possible type of waveform input for this network is the triangular type shown at the top of Fig. 6. A typical set of input and output waveforms for this network is given in Fig. 7, a study of which will reveal that the control of the output waveshape for the interval $0<t<T/2$ is performed readily by manipulation of the K_j and the connections to the two summing devices in the network of Fig. 6. However, once this portion of the wave is specified, the later portion of the output wave (i.e., for the interval $T/2<t<T$) is completely determined, and cannot be altered without changing the output wave for the first half-period.

If the wave to be generated can be drawn so that its minimum value occurs at the beginning of the period, and thus correspondingly at the extreme end of the period, this difficulty can frequently be overcome. The composite restrictive slope function generator shown in Fig. 8 will then provide the desired output waveshape, provided that the output of, say, generator 1 is entirely negative for the interval $T/2<t<T$. The rectifiers in the network will completely block the extraneous output from this generator during this interval, while allowing the desired output from generator 2 to pass to the output terminals. The direct voltage E_0 may be adjusted to restore the orginal d-c level in the generated wave. Conceivably, there exist such waveforms that the adjustment of the coefficients to produce the e_d' waveform of Fig. 8 will

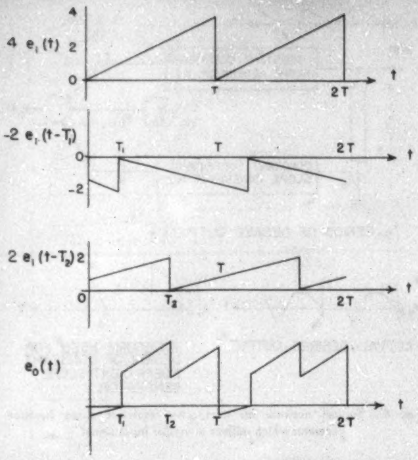

Fig. 9. Typical waveforms for constant coefficient slope function generator which utilizes saw-tooth input. The output $e_0(t)=4e_1(t)-2e_1(t-T)+2e_1(t-T)$, T = period of input $e_1(t)$

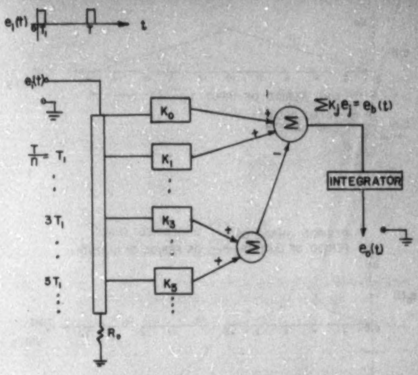

Fig. 10. Typical network for straight-line integration generator. Tap spacings all equal; n = positive integer

not provide an entirely negative output from the individual generators every alternate half-cycle of the input wave. In this case, the network would deliver an erroneous output every other full cycle of the output wave. Thus the composite-restrictive-slope function generator of Fig. 8 will perform satisfactorily for only a restricted class of desired output waveshapes.

One method which might appear to be a solution to the difficulty imposed on the function generator of Fig. 6 is to change the input to a saw-tooth shape so that the uncontrollable "second" half-cycle of the input signal is eliminated. A set of typical waveforms for this type of network is given in Fig. 9. Although this generated output signal might conceivably approximate a desired shape, one may imagine many shapes for which the sudden vertical changes in amplitude at the end of the component waveform periods would be intolerable.

If the saw-tooth input wave utilized in Fig. 9 were replaced by a saw-tooth pulse, the duration of which was small with respect to the period T of the wave, the resulting network configuration may be made to perform very satisfactorily for the generation of virtually all important periodic functions. Because this network and design procedure is a special case of the general polynomial approximation method, to be discussed in the next section, it will not be examined here.

The straight-line integration generator of Fig. 10 illustrates another slight variation of the basic tranversal network. When the tap spacings are all made equal to the square input pulse duration, there exists only one component of the K_jE_j sum which has a nonzero value at any one instant of time, illustrated by the typical waveforms shown in Fig. 11. This presents an appreciable advantage for the final experimental adjustment in that each coefficient clearly controls one section of the output curve exclusively. For the purposes of the general study here, the integrator is assumed to be ideal.

If the input signal to the straight-line integration generator of Fig. 10 were a conventional square wave with equal-duration ON and OFF intervals, the resulting performance would be imperfect every second half-cycle of the desired output. The basic reason for this is the lack of complete control of the component waveshapes throughout a full cycle of the input. This difficulty is in reality just a slightly different form of the difficulty associated with the constant coefficient slope function generator of Fig. 6.

POLYNOMIAL FUNCTION APPROXIMATION

It is assumed that most single-valued continuous periodic functions of engineering interest may be approximated over reasonable intervals of the independent variable by polynomial functions. The method utilizing this fact concerns itself with the discrete generation of polynomials to fit the given periodic function over prescribed portions of the fundamental period of the function. The resultant generated periodic function will then be the sum of these various polynomial functions, each valid over a different portion of the fundamental period of the resultant desired function. For the sake of concreteness, it will be assumed that each segment of the resultant desired function can be approximated closely by a fourth-degree polynomial. The first network to be designed is then a fourth-degree polynomial segment generator (PSG).

A general fourth-degree polynomial function of time may be expressed as

$$e_0(t)=A_0+A_1t+A_2t^2+A_3t^3+A_4t^4 \qquad (11)$$

in which the coefficients A_0, A_1, A_2, A_3, and A_4 are positive or negative real numbers. If it is possible to vary or adjust the A_j coefficients, then $e_0(t)$ may be made to approximate any real fourth-degree polynomial as needed for the particular segment under consideration. It is important to be able to obtain negative as well as positive A_j coefficients, for a restriction to positive values only would seriously hamper the type of representation possible.

A nonlinear resistance network described by Surber, Jr.,[4] and shown in Fig. 12 is able to produce an output voltage, defined by the equation

$$\begin{aligned} e_d(t) &= +K_a\left|e_i^a(t)\right|, \ e_i(t)\geq 0 \\ &= -K_a\left|e_i^a(t)\right|, \ e_i(t)<0 \end{aligned} \qquad (12)$$

The exponent a can usually be varied throughout the interval from one to four by the adjustment of r_3 and r_4 of Fig. 12.

A—Series output limiter with zero feedback resistance and its output-input characteristic

B—Adaptation to obtain direct voltage pulse only while PSG has an input signal

The double L-network of this figure contains two nonlinear Thyrite resistors as series elements, in addition to the two adjustable linear shunt resistance elements. Networks of the type illustrated in Fig. 12 would then be able to produce all of the terms on the right-hand side of equation 11, except the constant term A_0, provided the input is a linear function of time.

The insertion of the constant term A_0 into the network cannot be performed as simply as might be initially assumed. It is recognized that the proposed design utilizes several PSGs, each operating in turn, to form the segments that will then be joined to form the over-all desired waveform. At any instant, only one PSG will operate, so that it must have a proper A_0 term to join its boundaries with those of the preceding and succeeding segments. Using an average d-c component for all of the PSG units, or having a d-c term from one PSG present while another is operating would not permit the proper joining of the segments. Thus each PSG must have its proper A_0 term as an output, when and only when its segment is being contributed to the over-all waveform. To obtain the desired d-c output for each PSG, a special d-c generating device is needed which generates its output only when a nonzero input signal exists at the input to the PSG.

Fig. 13 shows the schematic diagram of a modified series output limiter which has the required properties for generation of the A_0 term. The output-input voltage characteristic indicates that the

output is constant and positive, or constant and negative, if the input has any nonzero negative or nonzero positive value respectively. For a zero input signal, this device delivers zero output. The more elaborate diagram on the lower portion of Fig. 13 indicates a form of the modified series output limiter which is compatible with the basic structure of the PSG.

The diagram of the complete PSG is given in Fig. 14. From this, it is seen that the output signal $e_0(t)$, is equal to the sum of the five terms constructed from the linearly increasing input. For the interval $0<t<T/n$, the output signal $e_0(t)$ is seen to be equal to the sum of the five terms as given in equation 11, because the positive and negative input signals are linearly increasing functions of time. The magnitude of the coefficients in this equation are readily obtained by adjustment of the potentiometers, while the sign associated with the coefficients is established by switching the respective term network input to the proper input channel.

The PSG of Fig. 14 is able to reproduce the general fourth-degree polynomial to a degree of exactness limited only by the linearity of the input and the exactness with which the coefficient can be established in the nonlinear networks. The fourth-degree polynomial is thus realized for the time segment $0<t<T/n$ indicated in the figure or, more particularly, for any interval of time during which the positive and negative input signals maintain a linearly increasing waveform.

There are many known ways by which a linearly increasing waveform may be established for a finite interval of time. In the generation of the final composite periodic waveform, it will be found convenient to have an input signal $e_1(t)$ which increases linearly with time for a finite interval, after which it is reduced abruptly to zero. This saw-tooth pulse is to be followed by a zero amplitude portion equal to $(n-1)T/n$ seconds, where T is the period of the wave to be formed, and n is the number of segments used in the approximation. By this mechanism, one PSG is able to act independently of the others in the complete waveform approximation circuit.

For the operation of the PSG, it is necessary to generate a train of positive-going triangular pulses together with the negative of this waveform. If a series of alternately positive and negative triangular pulses are available (such as might be generated from a sinusoidal source), the delay-line network of Fig. 15(A) will provide the required two sets of signals for the generator. If a series of exclusively positive triangular pulses is available, then the conventional operational amplifier inverter network of Fig. 15(B) may be used. These methods together with other known methods may

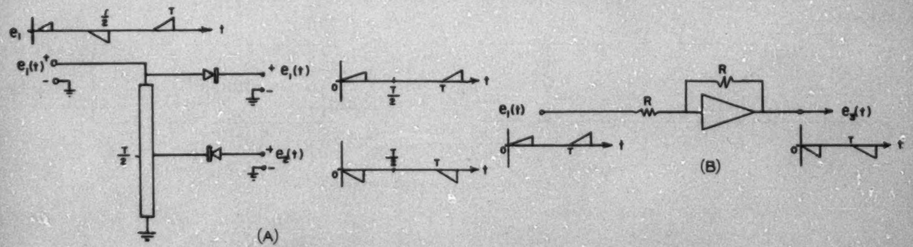

Fig. 15. Two methods for obtaining positive and negative input signals for PSG

A—Delay-line method B—Operational amplifier method

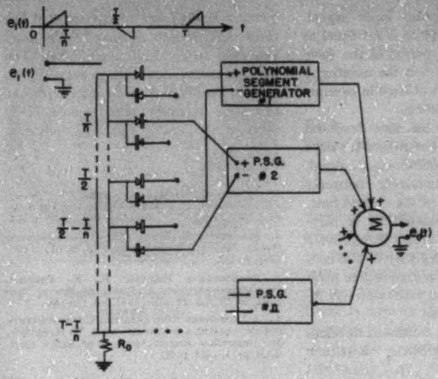

Fig. 17. Waveform approximation generator using n PSG and delay-line inverter network

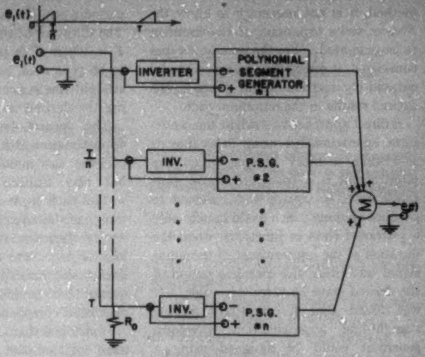

Fig. 18. Waveform approximation generator using n PSG and n inverters

be readily applied to the problem of producing the positive-going set of triangular pulses $e_i(t)$, together with its negative $[-e_i(t)]$.

The operation of the complete waveform approximation generator using n PSG may perhaps best be described in terms of a particular example. Suppose it is desired to reproduce a given periodic waveform to a very high degree of accuracy. Let this waveform as shown in Fig. 16(A) be divided into ten segments, and let each segment be approximated by a fourth-order polynomial function of time. This is equivalent to setting n, the number of waveform segments or the number of PSG equal to ten. The required duration of the triangular input pulse would then be $T/10$ where T is the period of the waveform to be approximated. One form of waveform approximation generator with the use of a delay-line inverter network which would produce this waveform is given in Fig. 17, in which n would be set equal to ten. An examination of this network shows that the PSG 1 delivers the entire output signal during the interval $0<t<T/10$, while the output from the other nine PSG units is zero for this interval. The PSG 2 unit delivers the entire output for the interval $T/10<t<T/5$, with the other units performing their functions in a similar manner. In this way, each PSG accurately and completely forms one segment of the resulting waveform.

Operation of the waveform generator should be relatively simple, if an oscilloscope is used. With the required contour for a given segment indicated on the screen by a mask or other contour, the corresponding PSG unit could be "knob-twisted" into the required shape with relatively little trouble after an initial learning period.

It is believed that n equal to 2 or 3 would give sufficient waveform accuracy for many applications. In this way the complexity of the network, and the amount of hardware needed in its construction would be reasonable. It seems that the one operational amplifier per A_0 unit in each of the PSG represents the main undesirable feature as regards equipment. It is recognized that these A_0 units may be conserved by increasing the degree of the polynomial through direct extension of the foregoing methods and thereby decreasing the number of PSG units needed to produce a given accuracy of waveform reproduction. This reduces the total number of operational amplifiers required, since only one is used per PSG unit.

Another possible form of the waveform approximation generator is that given in Fig. 18. The inverter network performs the function of producing $[-e_i(t)]$, given $[+e_i(t)]$ as an input signal. The operational amplifier method of producing this could be utilized, but this would increase the number of amplifiers required per waveform generator. The seriousness of the number of operational amplifiers in the final design would distinctly depend upon the capacity of the analog computer installation, and the magnitude of the problem being solved. It is possible that such refinements in the final design can be made that low-quality amplifiers may be built directly into the waveform approximation generator.

If only the first two terms of equation 11 were utilized in the PSGs, the waveform approximation generator would be the straight-line type mentioned earlier. Since A_0 and A_1 may be varied independently and made positive or negative in each segment of the generated wave, the resulting waveform approximation generator would possess complete flexibility. It would possess the same ease of experimental adjustment as was described for higher degree segment generators.

Conclusions

The delay-line Fourier synthesizer provides a relatively simple means whereby an irregular periodic waveform may be constructed from its Fourier series expansion. The accuracy with which the generated waveform adheres to the desired shape is limited by the number of terms of the Fourier series utilized, together with the accuracy with which the harmonics are generated.

The magnetic-core harmonic generator seems to offer particular promise as a tool for generating the harmonics needed in the delay-line Fourier synthesizer. The nonlinear-element harmonic generator offers a reasonably standard means of producing the harmonics, while the multiplier-type harmonic generator may prove to be of considerable value when improvements are made in the design of multipliers of relatively high-frequency range.

Function generation by waveform approximation provides an alternate method whereby an irregular periodic waveform may be produced. By this method, it is not necessary to know the Fourier series expansion of the function to be generated. For the generator types considered, it seems that an experimental cut-and-try method would produce the desired results in the minimum time.

A direct approach to straight-line waveform approximation using delay-line or short-time memory devices, when the input signal is a triangular wave, sawtooth wave, or square wave, seemed to produce systems which could handle only a restricted class of functions, when the duration of the nonzero part of the input signal was either the complete period of the desired wave or twice this value. It was found that a completely flexible straight-line approximation waveform generator could be designed using a periodic saw-tooth pulse input signal. The duration of the pulse is set equal to T/n, where T is the period of the wave to be generated, and n is the number of straight line segments utilized in generating the desired waveform.

The general form of the waveform approximation generator utilized the same periodic saw-tooth pulse input signal, but also utilized nonlinear networks so that each segment of the desired function can be approximated by a polynomial function of time of relatively high degree. The simplicity of the nonlinear network allows a high-degree polynomial to be generated with relatively inexpensive components.

It is hoped that the continued development of compact, efficient short-time memory devices will render some of the theoretical designs discussed both practical and economically justifiable. The high accuracy attainable in some of the designs may help to keep pace with the increasing accuracy reqnirements being asked of the analog computer industry.

Watt-Hour Meter for Two Phases of a 4-Wire Y 3-Phase System

A. M. McQUARRIE
NONMEMBER AIEE

Synopsis: A newly developed watt-hour meter for measuring energy in two phases of a 4-wire Y 3-phase system is essentially a single-phase meter with L-R phase-shifting networks in the current circuits. This paper describes the meter and shows performance and operating characteristics.

MANY UTILITIES in the United States and Canada use in high-load-density areas a 120/208-volt secondary network system instead of a radial system. Network systems are selected primarily to serve commercial loads in high-density areas. Apartment dwellings in such areas served by the network can use 120-volt 2-wire service for small appliances and lighting, but the addition of major appliances such as room air conditioners, ranges, and water heaters, dictates higher voltages than 120 volts, and 3-wire service is required.

Three-wire 120/208-volt service, consisting of two phases of the 4-wire Y 3-phase network, is readily available, but such a system has required the use of a 2-stator polyphase type of watt-hour meter. Because the cost of such a meter is more than double that of a single-phase meter, it is natural that utilities with extensive 120/208-volt network distribution systems should view favorably any efforts by manufacturers to search for new and lower cost methods of metering these circuits.

The voltage-current phase relationship of 120/208-volt network loads prevents standard single-phase meters from registering such loads correctly. However, by the addition of simple phase-shifting networks, a 3-wire single-stator meter may be modified to meter this type of service. The lower-cost single-phase meter construction results in substantial cost savings over that of a 2-stator meter.

Description

The meter shown in Fig. 1 is based on this principle. It consists essentially of a double-current-coil single-phase meter with inductance-resistance phase-shifting networks connected in the current coil circuits. Fig. 2 shows the stator assembly.

The internal and external connections of such a meter with its associated networks are shown schematically in Fig. 3. In each phase, the current is divided, with a portion passing through the current coil of the meter and the balance shunted around the current coil. The potential coil is connected across the lines.

It is noted in Fig. 3, that both 208-volt line-to-line, and 120-volt line-to-neutral loads must be metered. Under unity power factor conditions, the current in the 208-volt load is in phase with the voltage applied to the potential coil of the meter. The currents in the 120-volt line-to-neutral loads, however, are out of phase with the potential coil voltage.

By choosing the proper values of inductances and resistances in the networks, the currents in the current coils of the meter are adjusted in magnitude and phase angle, so that for 120-volt unity power factor loading, the current fluxes have the following relationships, which are required for accurate metering: 1. They are in phase with each other. 2. They are 90 degrees out of phase with the potential flux. 3. They are a predetermined ratio to the line currents.

Fig. 4 shows the approximate relationships of the current coil currents to the line currents and to the voltage applied to the potential coil, for unity power factor line-to-neutral loads.

In the case of 208-volt line-to-line loads, the currents in the current coils are no longer in phase with the voltage applied to the potential coil. At unity power factor load, the current in one current coil leads the voltage by approximately 30 degrees, while the current in the other current coil lags the voltage, as is shown in Fig. 5.

Paper 58-145, recommended by the AIEE Indicating and Integrating Instruments Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted March 27, 1957; made available for printing November 21, 1957.

Credit is due I. F. Kinnard for initial development work in 1927 on a meter based on the principle outlined in this paper.

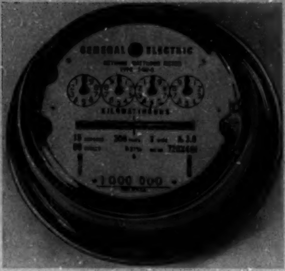

Fig. 1. Watt-hour meter for 120/208-volt network loads

Phase-Shifting Networks

In the development of this meter, the networks had to be made small and compact in order to keep the resistance low and the heating losses within acceptable limits. The minimum size of the reactors, however, is limited by the wire size necessary to carry the current without excess heating, the number of turns, the cross-sectional area of iron, and the air gap which is necessary to minimize the effect of the change of permeability of the iron with change of current. Furthermore, the reactors are proportioned to make use of the change of permeability with change of current for load compensation purposes.

The low impedance of the branches of the inductance-resistance networks (in the order of 0.003 ohm) requires that the contact resistance at the junction be kept very low and that it shall not change in service. For this reason, the connections are permanently silver-brazed in the factory. Adjustment of the individual load curves for phase balance and power factor is done at the factory. Field adjustment is limited to the usual full-load and light-load screws, which affect both phases together.

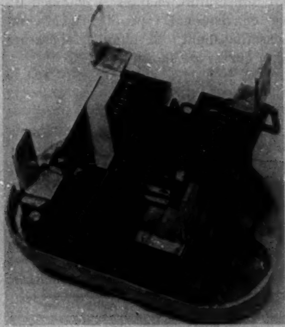

Fig. 2. Back view of stator assembly showing reactors and resistors

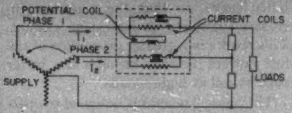

Fig. 3. Internal and external meter connections, showing phase shifting networks in current circuits

Balance between phases and lag adjustment are made by cutting between holes in the manganin resistance strips in the networks, thereby changing the values of resistance. Two such adjustable resistances are in each network, and the effect of changing these may be seen by reference to Fig. 6(B). The currents a_2 and b_2 are the currents in the two branches of the network in phase 2 with I_2 the resultant line current. The current a_2 through the current coil is maintained at approximately one half the line current I_2. The current b_2 is in phase with the voltage e_2 across the network, while a_2 lags by an angle ϕ, which is determined by the relative values of inductance and resistance in branch 2. The voltage e_2 across the network is shown only as a reference voltage to aid in understanding the relationships of the currents. It should be kept in mind that the line current is the forcing function in this network, and not the voltage e_2. By adjustment of r_2, the relative magnitudes of a_2 and b_2 are changed, as well as the angle ϕ between these currents. Adjustment of r_1 does not change the angle ϕ, but it does change angle θ, along with the relative magnitudes of the currents in the branches. It is seen that the two adjustments are not independent.

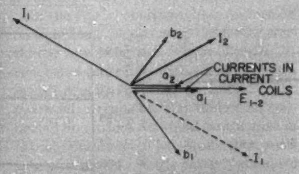

Fig. 4. Approximate relationship of currents in current coils to line currents and potential coil voltage for unity power factor line-to-neutral loads

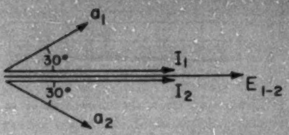

Fig. 5. Approximate relationship of currents in current coils to line currents and potential coil voltage for unity power factor line-to-line loads

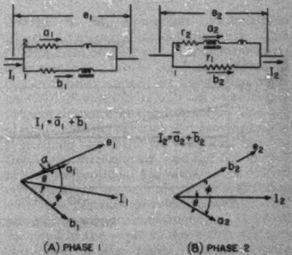
Fig. 6(A) shows a similar vector relationship for phase 1 in which $I_1 = a_1 + b_1$. In this case, due to the inductance of the current coil in branch 2, current a_1 is not in phase with the voltage e_1 across the network, but lags it by a small angle α.

The reactor required is not the same in each network. The inductance of the phase 1 reactor must be somewhat greater than that which was required in phase 2 for three reasons:

1. The reactor must compensate for the inductance of the current coil in the parallel branch.
2. A conventional type of lag plate is not used in the meter; hence, the useful potential flux lags the line voltage by an angle somewhat less than 90 degrees. Therefore the current in the current coil in phase 1 must lead the line current by a greater angle than would be required if the lag plate were retained.
3. The reactor must compensate for the lagging effect of the other network which is transformer-coupled through the current coil iron.

These factors operate in the opposite direction on the phase 2 circuit so as to reduce the amount of inductance required in the phase 2 reactor.

It is, of course, desirable to minimize the transformer coupling between the



(A) PHASE 1 (B) PHASE 2

Fig. 6. Relationship of currents in branches of networks to line currents

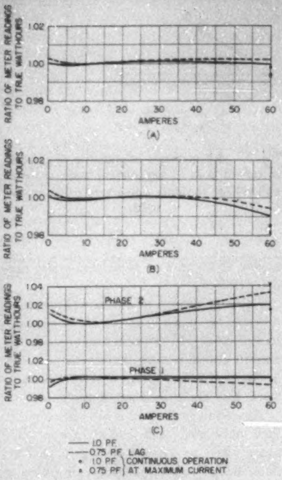


Fig. 7. I-62 meter load curves

A—Line-to-line loading
B—Line-to-neutral loading, phases energized
C—Line-to-neutral loading, individual phases

two networks in order to reduce the lagging effect and the heating losses. To help keep this coupling low, the conventional type of overload compensation is not used in this meter. Load compensation is obtained by making use of the change of permeability of the iron in the reactors with change of current.

The change in permeability of the iron at higher inductions has some effect on the calibration of the meter at higher loads, and this effect is used in the design of the reactors to compensate for the normal droop in the meter load curves. The phase 1 reactor is designed to operate only on the rising portion of the permeability curve, so that the reactance increases slightly with increasing current. This results in a greater proportion of the line current flowing through the meter current coil at higher loads.

The phase 2 reactor is designed to operate at higher flux densities at maximum line current. The lower iron permeability at maximum current causes a slight drop in the phase 2 reactance, and since the phase 2 reactor is in series with the phase 2 current coil, the meter load curve will tend to rise, as desired. In the case of the phase 2 reactor, however, the decrease in reactance with rising current is due mainly to increased flux leakage, and is indirectly due to the permeability change.

The low permeability of the iron in the reactors at low inductions tends to cause the meter to run fast on phase 2 and slow on phase 1 at light loads. The effect is kept within permissible limits by maintaining adequate air gaps in the magnetic circuits.

In addition to affecting the magnitudes of the currents in the current coil circuits, the change in impedance of the reactors with load introduces a small phase shift in the current coil currents. This affects the shape of the load curves at lagging power factors, as will be noted by referring to the load curves in Fig. 7(C). Low power factor loading on phase 2 will cause the meter to run fast at heavy loads; similar loads on phase 1 will cause the meter to run slow. With equal loading on both phases, these errors will tend to cancel, and the resultant low power factor load curve is essentially flat to maximum meter rating.

Temperature Effects

The resistances used in the networks are manganin strip, with a very low temperature coefficient. The copper in the reactance coils and in the current coils, however, has a temperature coefficient which will affect the magnitudes and phase angles of the currents in the two branches of each network, thereby introducing self-heat errors.

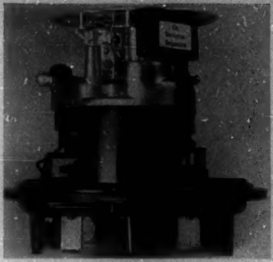

Fig. 9. Side view of meter, showing phase sequence indicator assembly

In the phase 1 network, Fig. 6(A), the copper is approximately the same in each branch. The self-heat error is therefore very small at unity power factor, but at low power factors an increase in temperature will cause an error in the slow direction, which amounts to about 2% at maximum current rating.

In phase 2, Fig. 6(B), copper is introduced into branch 1 of the network to compensate for the effect of the copper in branch 2. As in the other phase, the unity power factor self-heat error is thus made very small. Since the phase angle between the currents I_2 and a_2 tends to decrease with rise in temperature, there is an error at low power factors in the fast direction. This tends to balance out the low power factor temperature error in phase 1.

Temperature compensation for ambient temperature changes is obtained by the conventional type of magnet-compensating shunt. Resultant temperature error curves are shown in Fig. 8.

External Magnetic Field Error

In this meter, each of the *L-R* networks comprises a closed loop, which includes a current coil of the meter. It might be expected therefore that the meter would be very sensitive to external magnetic fields.

However, these loops are arranged so that the fluxes induced in the meter current coils due to external fields are in opposite directions, and cancel each other. The net effect of external fields on meter accuracy is very small, as is shown in Table I.

Phase Sequence

Unlike conventional 2-stator meters, this meter will register line-to-neutral loads accurately only if the phase sequence is positive, as shown in Fig. 3. Therefore precautions are required on installation to ensure that the phase sequence is correct. In addition, it is necessary to assure that the phases are not reversed in service due to wiring changes in other parts of the system.

To take care of this problem, one model of the meter is being developed with a phase rotation indicator incorporated in the form of a neon lamp which glows if the phase sequence is in the wrong direction. The phase rotation indicator assembly is shown in Fig. 9.

The phase rotation indicator consists of two resistors and a capacitor connected across the 208-volt supply, with the neon lamp connected from the junction of the two resistors to ground. The values of resistances and capacitance are so chosen that, with incorrect phase rotation, 120 volts are applied across the neon lamp, causing it to light. With proper phase rotation the voltage across the lamp is approximately zero.

Thus, the meter installer is able to determine readily, at the time of installation, whether the phase rotation is correct. If by any chance the phase sequence should become reversed, due to wiring changes in other parts of the service, the neon lamp will glow and warn of the condition.

Performance and Operating Characteristics

The performance and operating data of the single stator network meter are compared with that of a typical 2-stator network meter of the same rating in Table I. Characteristic curves of the single stator meter are given in Figs. 7, 8, and 10.

Calibration and Test Procedure

The field test procedure for the single stator network meter is very similar to that for a single-phase 3-wire meter, with the two current circuits connected in series. As mentioned, the only adjustments are those of full load and light load, which are made in the same manner as with a single-phase meter. Thus, the routine field testing of the meter is much faster and more economical than that of a 2-stator meter.

In the factory, calibration is performed on individual phases with the meter connected to a balanced voltage 3-phase Y-connected generator, with all three phases loaded equally from line to neutral. The potential circuit of the meter is connected line to line, as would be the case in actual operation. The standard meter is a conventional single-phase standard type, and is inserted in series with the particular current circuit being adjusted. The potential circuit of the standard is connected from phase to neutral. For lag calibration, 0.5 power factor is obtained by cross phasing.

With the voltage on the standard being of a different magnitude and at a 30-degree phase angle from the voltage applied to the meter under test, the importance of precise control of these supply voltages can be understood. However, the separate 3-phase Y-connected generators supplying each test table take care of this problem automatically, with no attention from the operator.

Although no independent adjustment of the individual phases is possible in the field, a spot check of the calibration of each phase by the utilities is, of course, desirable. Such checks may readily be made with the use of single-phase meter standards, provided the proper voltage magnitude and phase relationships are maintained between the meter being tested and the standard.

Summary

This paper shows how the addition of phase-shifting networks to the current circuits of a 3-wire single-stator meter makes it applicable for measurement of power in two phases of a 4-wire Y 3-phase system.

The meter is proposed for domestic network system loads, where voltages are balanced, and power factor is normally higher than 0.75. Such loads include window-type air conditioners and major electric appliances, as well as small loads such as clocks and night lights. The smaller loads will be applied on individual phases, whereas the heavier loads will normally be on both phases. The performance is shown to compare very favorably with more costly 2-stator meters.

◆

Discussion

George B. M. Robertson (Philadelphia Electric Company, Philadelphia, Pa.): The development of the 3-wire single-stator watt-hour meter for use in the measurement of line-to-neutral as well as line-to-line loads on 120/208-volt 3-wire services represents a distinct advance in the industry. The use of phase-shifting networks for accomplishing this result represents an ingenious innovation in the metering art, and the elimination of the conventional lag plate and overload compensation by combining this function with the reactors provides desirable simplification in meter construction. The data included in the paper indicate that the performance of the meter compares quite favorably with that of the 2-stator meters that have been necessary in the past for correct measurements on this type of service.

Not included in the paper are data on the effects of variation in frequency. This may have been omitted because the stability of the large interconnected systems of today is such as to render this feature of negligible importance. However, the effects of frequency variation serve as a valuable index to meter performance on circuits having harmonics. I would therefore ask Mr. McQuarrie whether he has any test data on the effects of frequency variation.

From the point of view of practical operation it may be well to stress that while the meter will measure correctly line-to-neutral and line-to-line loads on two phases of 120/208-volt 3-phase 4-wire circuits, it cannot be used for other types of service which are at times metered with the conventional 2-stator network meter. Thus the new meter cannot be used on 3-phase 3-wire, 2-phase 3-wire, or single-phase 3-wire circuits. However, for the purpose for which it is intended, the use of the new meter will represent a distinct economy over the 2-stator meter for those utilities that have extended 4-wire Y 3-phase systems.

C. V. Morey (Consolidated Edison Company of New York, Inc., New York, N. Y.): The development and production of a commercially practicable single-stator watt-hour meter for measurement of 3-wire service from a 3-phase 4-wire 120/208-volt distribution system is a revolutionary step forward in watt-hour metering and has a decided significance for utility companies from the standpoint of economics. The General Electric Company is to be commended for its accomplishment, and the author for his clarity in presenting the technical details of construction and operation.

The economic factor is particularly important in the case of the Consolidated Edison Company of New York, since we have over 2,000,000 customers supplied from a 3-phase 4-wire system.

In the early days of 3-phase, 4-wire networks, the only meter available for 120/208-volt (so-called open-Y) service, was the bulky, cumbersome, and rather expensive 2-stator polyphase meter normally used for 3-phase delta or 2-phase power measurement. Simplified and more compact revisions of this 2-stator meter were produced later on and with the continuous advancement of the metering art, 2-stator meters are presently available in mounting frames and housings not much larger than those for single-stator meters. However, meters of the 2-stator construction are naturally more costly to build than single-stator meters, and this differential is further increased because of much lower volume of production. Such meters, for 3-wire 120/208-volt application, have generally sold for about $2^{1}/_{2}$ times the price of single-stator meters for 2-wire 120-volt or 3-wire 120/240-volt application. Because of this difference in price, new residential customers on the Consolidated Edison Company system were, up to 3 or 4 years ago, practically all served at 120 volts, 2-wire, so that less costly single-stator 2-wire meters could be utilized.

With increased use of heavy appliances and room air conditioners, however, 2-wire service came to be considered inadequate in our territory for residential loads. This inadequacy applied both to new installations and to existing cases where customers were rewiring in order to provide large risers for apartment house tenants. The potential requirement for new meters for 3-wire 120/208-volt installations thus became extremely large, the rate of use of such meters now being in excess of 50,000 per year. As a consequence, the meter manufacturers were urged to develop a more economical meter which would be suitable for this application, and the type *I-62* meter is the result of the successful effort made by the General Electric Company in this direction.

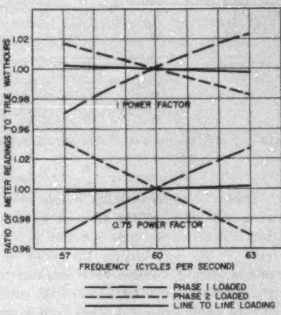

Fig. 11. I-62 meter frequency curves

The only practical difficulty with this new meter is the necessity for wiring the two phase conductors to it in a particular phase sequence and ensuring that such phase sequence is maintained as long as the meter remains in service. As stated in the author's paper, phase sequence must be correct or 120-volt 2-wire loads will not be registered properly. This difficulty has been overcome in the case of Consolidated Edison Company by making use of the color-coded wiring required to be installed by contractors. The colors are white, black, and red for 3-wire service, and white, black, red, and blue for 4-wire service; white being the neutral conductor in both cases and the other colors the phase conductors. Where the supply to a single or multifamily building is 3-wire, the color combination of the phase conductors will always be red-black. Where the supply to the building is 3-phase, 4-wire, three different color combinations (red-black, black-blue, blue-red) may be derived to supply 3-wire service to different customers. Wiring prints were issued to all contractors instructing them as to how each color combination should be connected to meter-mounting terminals. When the Company connects the colored phase conductors to the distribution system at the service point, the connection is made so that black leads red where the service is 3-wire, and so that black leads red leads blue where the service is 3-phase 4-wire. To aid contractors and also Company inspectors, the Company developed a new form of phase sequence indicator, about as large as a good-sized fountain pen, and had it made in quantity. This device is used to make a final check for phase sequence at the meter mounting before the meter is installed.

The addition of the neon lamp indicator referred to in the paper, the circuit of which is constructed along the same lines as the phase sequence indicator just mentioned, will afford a convenient means for meter indexers to note and report any case where the phase sequence has been accidentally or intentionally reversed.

The new meter, besides costing less, is smaller, lighter, and easier to handle than a conventional 2-stator meter and the fact that adjustments for power factor and equality of circuits are preset by the manufacturer makes it about equivalent to a 3-wire 120/240-volt single-stator meter for simplicity of test and calibration.

A. M. McQuarrie: Mr. Robertson's question with respect to the effects of variation in frequency can best be answered by reference to the frequency error curves shown in Fig. 11.

As would be expected, because of the inductances in the phase-shifting networks, the individual phases of the meter are somewhat frequency sensitive. However, since the frequency errors on the individual phases are in opposite directions, these errors cancel out when both phases are loaded. The result is a practically flat frequency error curve when the phase loads are balanced or when the load is 208 volts line to line.

Mr. Morey has shown how the correct phase rotation at the meter may be ensured during installation by means of color coded wiring. Such a system should be applicable by any utility considering the use of single-stator network meters, thus minimizing the application difficulties.

A Stabilized D-C Differential Transistor Amplifier

LOUIS DEPIAN
ASSOCIATE MEMBER AIEE

RICHARD E. SMITH
ASSOCIATE MEMBER AIEE

TRANSISTORS present many advantages over vacuum tubes. Though they may be substituted for tubes in amplifiers, oscillators, pulse generators, pulse counting circuits, etc., they only amount to one hundredth of the weight of tubes, one thousandth of the volume, they consume one tenth of the power, and their average life is shown to be longer.

In certain fields, however, their application has been limited by their inherent sensitivity to temperature. This is particularly true in d-c and switching amplifiers, where changes in the amplifier operating point may cause outputs which are indistinguishable from those caused by actual input signals.

Temperature Variations of Transistor Parameters

An elementary, transistor d-c amplifier, as shown in Fig. 1, may be characterized by three parameters α_{cb}, I_0', and r_d. Each of these parameters depends, in general, on temperature.

The amplification factor for the common emitter circuit α_{cb} can be shown to be nearly independent of temperature.[1] Fig. 2 shows an experimental curve for the variation of α_{cb} as a function of temperature. While α_{cb} is nearly independent of temperature, r_d does show a small variation as the ambient temperature is changed (Fig. 3).

These variations are insignificant compared to the dependence of I_0' on temperature. I_0' is the collector current when the base current is zero and the collector-to-emitter voltage is of the order of magnitude of a few volts. It is related to I_{co}' (collector current when emitter current is zero and when collector-to-base voltage is of the order of magnitude of a few volts) by

$$I_0'=I_{c0}'(1+\alpha_{cb})$$

It can be shown[2] that I_{co}', and consequently I_0', will increase at the rate of about 10% per degree centigrade at room temperature. Fig. 4 shows experimental curves for the variation of I_0' as a function of temperature. It is evident that the variation of I_0' with temperature is much greater than that of α_{cb} or r_d, and it is thus the primary cause of temperature dependence of the operating point. Any practical d-c or switching amplifier must compensate for this variation.

If, in the amplifier of Fig. 1, I_0' is increased by a factor of b, the operating point will drift, and the collector current will increase by a factor of a

$$\alpha=\frac{1+\lambda b}{1+\lambda} \tag{1}$$

where

$$\lambda=\frac{r_d I_0'}{E_{ce}}\,\frac{1}{1+\dfrac{\alpha_{cb} r_d}{R_f}} \tag{2}$$

This variation in i_c is shown in Fig. 5. Changes in the collector current with variation in α_{cb} and r_d may be calculated in a similar manner.

Compensating Circuits

There have been several circuits devised for temperature stabilization of d-c transistor amplifiers. One of the more common methods is use of direct voltage and current feedback.[1] The voltage feedback methods are limited in their use to cases where the d-c resistance in the collector circuit is high. On the other hand, the current feedback method has a greater range of design freedom but is limited to cases where the d-c resistance in the collector circuit is low. In general it may be said that feedback achieves temperature stabilization at the expense of current gain.

Feedback in individual stages of amplification may be used to compensate partially for transistor-parameter variations. Two stages may then be coupled together so that the parameter variations in one stage will modify the feedback in the other stage and temperature-stabilize the amplifier.[3] This method, however, requires the use of transistors with a high-current amplification factor and low leakage current. Furthermore, none of these circuits provides zero output with zero input unless special circuitry has been added.

Other methods of stabilization make use of nonlinear temperature characteristics of other devices for compensation.[4-6] However, these have the disadvantage that each transistor requires a matched element for temperature compensation.

The Differential Amplifier

It is shown in the foregoing that the main variation in transistor parameters occurs in I_0. The method described here eliminates this variation by employing two transistors in the amplifier shown in Fig. 6. This circuit accomplishes the compensation by subtracting the voltages due to I_{01}' and I_{02}' across R_{L1} and R_{L2}, respectively. On the other hand, the effect of an actual input signal is not cancelled and will appear as an output. The output voltage V_0 is usually given by

$$v_0=i_s\left(\frac{\alpha_{cb_1}R_{L_1}}{1+R_{L_1}/r_{d_1}}+\frac{\alpha_{cb_2}R_{L_2}}{1+R_{L_2}/r_{d_2}}\right)+ E_{ce}\left(\frac{1-\alpha_{cb_1}R_{L_1}/R_{f_1}}{1+R_{L_1}/r_{d_1}}+\frac{1-\alpha_{cb_2}R_{L_2}/R_{f_2}}{1+R_{L_2}/r_{d_2}}\right)+ I_{0_1}'\frac{R_{L_1}}{1+R_{L_1}/r_{d_1}}-I_{0_2}'\frac{R_{L_2}}{1+R_{L_2}/r_{d_2}} \tag{3}$$

For compensated operation only the first term should exist and the other be eliminated. This is readily achieved if

$$\frac{R_{L_2}(1+R_{L_1}/r_{d_1})}{R_{L_1}(1+R_{L_2}/r_{d_2})}=\frac{I_{0_1}'}{I_{0_2}'} \tag{4}$$

and

$$\frac{1-\alpha_{cb_2}R_{L_2}/R_{f_2}}{1+R_{L_2}/r_{d_2}}=\frac{1-\alpha_{cb_1}R_{L_1}/R_{f_1}}{1+R_{L_1}/r_{d_1}} \tag{5}$$

If $R_{L_1}/r_{d_1}<<1$ and $R_{L_2}/r_{d_2}<<1$, the above expression can be simplified

$$\frac{R_{L_2}}{R_{L_1}}=\frac{I_{01}'}{I_{02}'} \tag{4A}$$

and

$$\frac{\alpha_{cb_2}R_{L_2}}{\alpha_{cb_1}R_{L_1}}=\frac{R_{f_2}}{R_{f_1}} \tag{5A}$$

effectively eliminating the effects of r_d variations, since the output voltage is then

$$V_0=i_s(\alpha_{cb_1}R_{L_1}+\alpha_{cb_2}R_{L_2}) \tag{6}$$

Notice that both transistors contribute in current amplification. This circuit eliminates the effect of r_d variations only for small values of R_L (of the order of magnitude of $1K$). If higher values of R_L are desirable, the circuit may be modified, as shown in Fig. 7. Here the output voltage is

Paper 58-192, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted October 23, 1956; made available for printing December 9, 1957.

LOUIS DEPIAN is with George Washington University, Washington, D. C., and RICHARD E. SMITH is with Carnegie Institute of Technology, Pittsburgh, Pa.

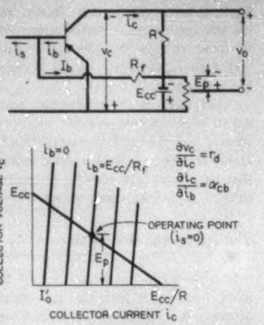

Fig. 1. Conventional common-emitter PNP junction transistor amplifier and characteristic curves

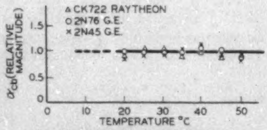

Fig. 2. Current-amplification factor α_{cb} (common emitter) as function of temperature

$$V_0=i_s\left(\frac{\alpha_{cb_1}R_{L_1}}{1+\beta_{01}}+\frac{\alpha_{cb_2}R_{L_2}}{1+\beta_{02}}\right)+E_{cc}\left(\frac{1}{1+\beta_{01}}-\frac{1}{1+\beta_{02}}\right)+I_{01}'\frac{R_{L_1}}{1+\beta_{01}}-I_{02}'\frac{R_{L_2}}{1+\beta_{02}} \quad (7)$$

where

$$\beta_{01}=R_{L_1}\left(\frac{1}{R_{f_1}}(1+\alpha_{cb_1})+\frac{1}{r_{d_1}}\right)$$

$$\beta_{02}=R_{L_2}\left(\frac{1}{R_{f_2}}(1+\alpha_{cb2})+\frac{1}{r_{d_2}}\right) \quad (8)$$

For compensation

$$\beta_{01}=\beta_{02} \quad (9)$$

and

$$\frac{R_{L_2}}{R_{L_1}}=\frac{I_{01}'}{I_{02}'} \quad (10)$$

From equation 8 it can be seen that the elimination of the r_d variation may be effected through R_{f_1} and R_{f_2} rather than through R_{L_1} and R_{L_2}. If

$$\frac{\alpha_{cb}}{R_f}>>\frac{1}{r_d} \quad (11)$$

then equation 9 is simplified to

$$\frac{\alpha_{cb_1}}{\alpha_{cb_2}}\frac{R_{f_2}}{R_{f_1}}=\frac{R_{L_2}}{R_{L_1}} \quad (9A)$$

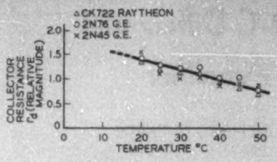

Fig. 3. Collector resistance r_d (common emitter) as function of temperature

The output voltage is then

$$V_0=i_s\left(\frac{\alpha_{cb_1}R_{L_1}}{1+\alpha_{cb_1}R_{L_1}/R_{f_1}}+\frac{\alpha_{cb_2}R_{L_2}}{1+\alpha_{cb_2}R_{L_2}/R_{f_2}}\right) \quad (12)$$

Notice that the output voltage here is lower than that of equation 6.

The amplifiers of Figs. 6 and 7 require different values of R_L and R_f for each transistor in order to achieve stabilization.

It is possible to obtain compensation with the same value for R_L for each transistor by the insertion of a small resistance, as shown in Fig. 8.

The compensation criteria here are

$$1+\frac{R_0}{r_{d_1}}=\gamma=\frac{I_{01}'}{I_{02}'} \quad (13)$$

and

$$\frac{\alpha_{cb_1}}{\gamma R_{f_1}}=\frac{\alpha_{cb_2}}{R_{f_2}} \quad (14)$$

provided that

$$\frac{\alpha_{cb}}{R_f}>>\frac{1}{r_d} \quad (15)$$

Then

$$V_0=i_s\left(\frac{\alpha_{cb_1}R_L}{1+\alpha_{cb_1}R_L/R_{f_1}}+\frac{\alpha_{cb_2}R_L}{1+\alpha_{cb_2}R_L/R_{f_2}}\right) \quad (16)$$

Equation 13 shows that if the variation of r_d with temperature is pronounced, the amplifier of Fig. 7 should be used rather than that of Fig. 8.

The amplifiers described are capable of supplying power to a load resistance connected across their output terminals. In all the circuits described the conditions for temperature stabilization are the same as those obtained for the unloaded cases. The only modification is a factor required for the output voltage. For example, if a load resistance R_c is connected across the output terminals of the amplifier shown in Fig. 6, the output voltage expression in equations 8 becomes

$$V_0'=\frac{1}{\alpha}V_0 \quad (17)$$

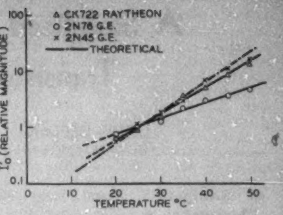

Fig. 4. I_0' as function of temperature

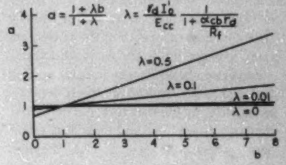

Fig. 5. Variation of collector quiescent current versus variation of I_0'

where

$$\alpha=1+\frac{R_{L_1}}{R_c(1+R_{L_1}/r_{d_1})}+\frac{R_{L_2}}{R_c(1+R_{L_2}/r_{d_2})}$$

If the specified conditions for equations 4(A) and 5(A) to hold are satisfied, then the output voltage V_0' is simplified to

$$V_0'=i_s\frac{R_c}{R_c+R_{L_1}+R_{L_2}}(\alpha_{cb_1}R_{L_1}+\alpha_{cb_2}R_{L_2}) \quad (18)$$

If a load R_c is applied to the amplifier shown in Fig. 8, the output voltage becomes

$$V_0'=\frac{R_c i_s}{R_c+\frac{R_L}{\gamma+\alpha_{cb_1}R_L/R_{f_1}}+\frac{R_L}{1+\alpha_{cb_2}R_L/R_{f_2}}}\left(\frac{\alpha_{cb_1}R_L}{\gamma+\alpha_{cb_1}R_L/R_{f_1}}+\frac{\alpha_{cb_2}R_L}{1+\alpha_{cb_2}R_L/R_{f_2}}\right) \quad (19)$$

One may obtain the output voltage in the loaded case for the amplifier shown in Fig. 7 from equation 19 by setting $\gamma=1$ and putting in the appropriate R_{L_1}'s and R_{L_2}'s where they belong. Thus, by the appropriate use of equations 17, 18, and 19, it is possible to obtain the current gain for any single-stage differential amplifier with any load, and, by the proper use of the conditions mentioned in this paper, to build a temperature-stable d-c transistorized amplifier. This also indicates that it is possible to cascade these amplifiers without any difficulty.

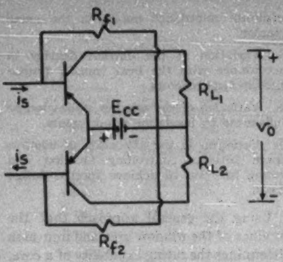

Fig. 6. Differential amplifier with fixed bias

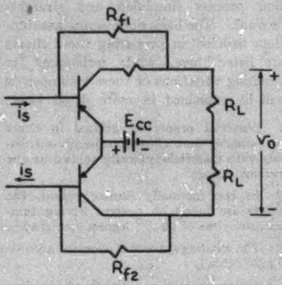

Fig. 7. Differential amplifier with self-bias

Design of a Single-Stage Differential Amplifier

To design a differential amplifier it is necessary to know the current gain and the load resistance to be used. By making some rough approximations and using equations 18 and 19 it is possible to arrive at some rough figures for α_{cb}, and thus choose a transistor. An examination of these two expressions makes clear that this is the only parameter that affects the gain of the difference amplifier. When a transistor has been selected, the parameters for the two transistors must be determined. It is actually only necessary to determine experimentally the I_0's for the transistors by measuring the collector current when the base current is zero and the collector-to-emitter voltage is of the order of a few volts. The other parameters can be calculated from manufacturers' curves. Then from equations 4(A), 10, or 13 the ratio of the R_L's is obtained, or the value of R_0, as the case may be. Of course, it is necessary to check whether the conditions for the application of each of these equations are met by the rough design already outlined, but this is easy to do once the transistor is chosen and the manufacturer's curves are obtained.

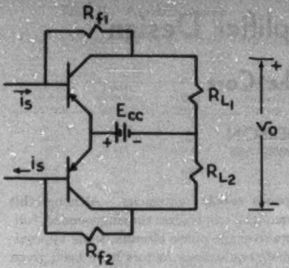

Fig. 8. Modification of differential amplifier with self-bias

With the determination of the R_L's or R_0 one can then refine the original, rough design by using the methods already available for vacuum-tube amplifiers and the expressions given in the foregoing. When the amplifier is completed, the second adjustment, indicated by equations 5(A), 9(A) and 14, can be made experimentally by varying one of the bias resistors so that the output voltage is zero when the input signal is zero.

If a double power supply is available, the differential amplifier suggested by Hurley[1] can be used.

Experimental Results

A differential amplifier was constructed by the use of the procedure outlined. The current gain was measured as a function of ambient temperature. The results of this measurement are shown in Fig. 9.

For a demonstration of the effectiveness of this method, one transistor was removed, and the output current was experimentally determined for the single-transistor amplifier, and then for the differential amplifier. The results are plotted in Fig. 10.

Conclusions

This paper shows that reliable temperature-stable, d-c transistor amplifiers can be built with differential amplifiers. It is, of course, possible that other circuits be used as well, but the differential amplifier does not require any highly special measurements to be set up, nor does it have severe limitations concerning loads. The procedure allows the designer much freedom, and requires no tedious calculations. Each transistor that is used contributes to the gain of the entire amplifier, and no device is employed as a temperature compensator alone. Stages may be cascaded as easily as those of a single-stage d-c amplifier, and these interactions can be predicted from the expressions indicated.

Magnetic-Amplifier Design

Part I—The Core

R. E. ANDERSON
ASSOCIATE MEMBER AIEE

Synopsis: A practical approach is developed for the design of the toroidal magnetic amplifier, based on synthesizing the design from design charts, and thus avoiding the necessity of having available detailed data from previous equipment. Starting with a known power supply frequency, together with a desired gain and time constant, the load voltage and current are utilized in determining the core. With the core specified, additional charts are presented for the winding layout design. The usual heat transfer and resistance computations serve as a check on the initial design synthesis and these complete the design process. A straightforward and practical step-by-step design procedure is outlined. This paper, the first of two on this subject, is concerned with the design approach and the core determination. Part II will cover the windings and the completion of the design.

THE EXCELLENT SUITABILITY and fine performance of the magnetic amplifier in applications requiring ruggedness and reliability have led to increasing use of this device as a control and instrumentation component. From this situation arises a need for information and methods to be used in the design of the magnetic amplifier as a system component. A number of articles[1-8] have discussed specific problems in the design area, while other authors[9-10] have discussed some of the general aspects of design. In view of this background, it is the purpose here to present an organized collection of data which may be used in a practical step-by-step manner to design the toroidal magnetic amplifier, thus bringing together the information necessary for undertaking the design process. These data will cover magnetic amplifiers of all sizes for operation with various power supply frequencies. Although this material emphasizes the single-ended, full-wave single-phase circuits, some approximate equivalence factors have been given for various other circuits. The scope of this work will be limited to the self-saturating type of magnetic amplifier. The material is directed toward designing the circuit and reactor component while leaving information on core materials, wire, rectifiers, and heat transfer to commercially available information and the published literature in these fields of technology.

Design Technique

A group of charts has been prepared to permit the design of a toroidal amplistat without reference to previous designs. Perhaps it would be in order to discuss the design philosophy on which these charts are based and the principles which were employed in the preparation of the charts. Of course, it is well known that the size of an electromagnetic device depends upon its power rating or its volt-ampere rating. The exact manner in which the rating influences the size of a magnetic amplifier might be explained a little more clearly as follows: In a given reactor, to be used as a component in the magnetic amplifier circuit, certainly it is evident that the voltage rating is directly proportional to the cross-sectional area of the iron multiplied by the number of turns; while the current-carrying capacity is directly proportional to the area of the window, or of the copper, used in the conductors divided by the number of turns. Thus, it may be seen that the product of the window area times the iron area will be proportional to the volt-ampere rating of the reactor. (For more details see Appendix I.) In practice, naturally, this relationship is tempered by the fact that there are certain parameters whose magnitude varies with the size of the reactor. Some of the more important of these factors may be listed as follows:

1. Variation of the stacking factor with different thicknesses of core material.
2. Variation of the current density to maintain impedance match in the small reactor.
3. Variation of the current density in accordance with the heat transfer limitations in large reactors.
4. Variation of the window utilization as influenced by insulation requirements.
5. Variation in the allocation of window space between controlling function and gating function to achieve specific design goals.

Using the general approach that the product of the window area and iron area determines the rating capability of a core, together with laboratory meaurement of the factors just listed, design charts have been prepared to make the design calculation process simplified and straightforward. The basic engineering assumptions utilized in preparing these charts are listed here, while techniques for handling variations of these assumptions will be explained in more detail later:

1. Material properties utilized in chart preparation were chosen to be commensurate with materials typically applied at the various ratings.
2. In the thermally limited region, the charts are based on designs having temperature rises of 55 C (degrees centigrade).
3. The winding space was allocated according to Table I.
4. Approximately one eighth of the line voltage is assumed lost to after-saturation inductance. (Smaller drops may be achieved under favorable conditions.)
5. The chart is based on a typical design insulated for a 1,500-volt hi-pot (high-potential) test.
6. The copper area is assumed 20% allocated to all control functions, leaving 80% for the gating function.

To give the reader an understanding of the organization of this paper, the design procedure will now be summarized briefly before proceeding to the specific details.

From the rating of the magnetic amplifier, a core determination chart is used to determine the product of the core window

(*Continued on page 164*)

area times the core iron area for any design flux density. (For the rating method upon which the charts are based see Appendix II.) The actual product of the iron area and window area is computed by utilizing materials chosen on the basis of the desired dynamic performance, the cost, etc., and by utilizing a core material thickness which is chosen as suitable for the power frequency of operation.

Table II lists some of the available cores from which an actual core is chosen. In Part II techniques are given for computing the number of turns and wire size to meet either a voltage or a load resistance specification. This evaluation is based on equation 1,[11] the transformer voltage equation, and on the available window dimensions.

$$E_s = 4fN_GB \times A_{Fe}(2.54)^2 \times 10^{-8} \qquad (1)$$

Once the core size is known and the wire size chosen, the layer-turns chart, also in Part II, may be used to find the number of turns in the first layer. The winding design continues by using a known number of turns in the first layer, together with a desired total number of turns to enter a chart which gives an equivalent number of layers. From this point, the winding hole size may be determined, while information is given on typical winding capabilities of various toroidal winding machines. With this sequence as a background, the actual use of the design charts will be explained in more detail, together with a step-by-step procedure for undertaking the design.

Core Design

The core determination chart, Fig. 1, is used to determine the core size. Two aspects of this chart deserve special mention. As may be seen from an examination of the chart, one enters this chart on the abscissa axis at the desired maximum rating of the magnetic amplifier divided by the minimum supply frequency. This technique permits the use of a single chart for all frequencies of power supply. For an amplistat circuit with a resistive load, multiply the actual rating by the factor shown in Table III to obtain the rating of a pair of the same reactors in single-phase full-wave single-ended circuits. It may be seen that core sizes listed on the ordinate axis of this chart express the core size in kilogausses multiplied by inches to the exponent four. By employing this method of incorporating flux density into the size figure, the chart may be used with all core materials. By studying the table of dynamic power gains, Table IV, one may choose materials having performance and cost suitable for

the specific application. Obviously, dividing the size, kilogausses times inches to the fourth power, found in the chart by the design flux density, gives the net core size in iron area times window area. The approximate design densities in Table V may be used in establishing the design flux density for the material chosen. From this net core size, one may find the gross core size by dividing by the stacking factor for the thickness of material used. The designer should consult the manufacturer's data for the actual core used, although Table VI gives typical values.

Corrections should be made to the determined gross core size if any of the design aspects deviate from the assumptions used in the preparation of the chart. These items will now be discussed in more detail.

The winding space allocation assumed in the preparation of the chart was based on the study of present design practice. This allocation is shown in Table I. It is interesting to note that, unlike the windings of a cylindrical coil,[7] the space allocation in a toroidal winding is relatively independent of size. This situation arises because of the differences in insulation requirements of small sizes, as well as the economics of manufacture in winding the larger sizes. Of course, the actual space allocations to be used depend upon the winding machine capabilities and the economics of the particular manufacturing operation. The gross core size required will vary inversely with the per cent of the total window space allocated to copper. This window space allocation may be influenced by the insulation requirements, as well as by the winding machine capabilities. As the required hi-pot level is increased, more of the window space must be allocated to the necessary insulation. Fig. 2 gives approximate factors by which the gross core size should be divided to correct for insulation level. The core determination chart is based on designs having temperature rises of 55 C. For high-temperature materials the size

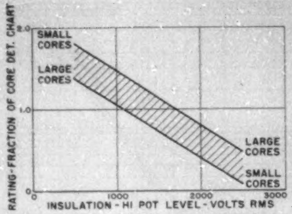

Fig. 2. Correction chart for insulation level

should be reduced and the current density raised to reach the desired temperature level, an advantage to be obtained only in the thermally limited region of design. Furthermore, the core determination chart, Fig. 1, is based upon 20% of the total copper cross-sectional area being used for control purposes; an allocation normally found in practice. For maximum power gain, 50% of the copper area is used for the control winding, while minimum size and maximum dynamic power gains are obtained with a minimum of space given to the control winding.

In thermally limited designs, the minimum space just mentioned is established by the thermal current capacity of the control conductor and it results in approximately 100 divided by K_{AT}, per cent of the total copper area given to the control winding. The gross core size should be corrected for the copper allocation by being multiplied by 80 divided by the actual per cent of copper to be allocated to the gate. Having corrected the gross core size for the various assumptions used in the chart, one may proceed to choose the actual core dimensions by using Table II. Obviously, with the product of areas known, any commercial catalog of cores could also be used in making this choice. Thus, with the core determined, one proceeds with the layout of the winding design as described in Part II of this paper.

Step-by-Step Design Procedure

The process for core determination in the design of the magnetic amplifier just described may be summarized as a step-by-step procedure, outlined in Table VII.

Appendix I. Output Versus Size

The relationship between rated output and size may be analyzed as follows: Assuming an inductive d-c load such as the field of an exciter, a relay, etc., the power dissipated in such a typical load is

$$\text{Rating} = P_o = E_L I_o \qquad (2)$$

where E_L is the average value of load voltage and I_o is the d-c component of output, and in which

$$E_L = E_o \times \frac{R_L}{R_o} = E_o \times \frac{n}{n+1} \qquad (3)$$

or

$$E_L = A_{Fe} s_f B_s (4fN_G) \times 10^{-8} \frac{n}{n+1} \qquad (4)$$

and

$$I_o = I_G k_f \qquad (5)$$

$$= \frac{A_w \times J \times G\, k_f w_f}{N_G} \qquad (6)$$

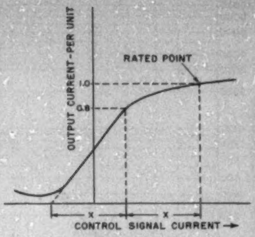

Fig. 3. Rating point diagram

Thus, combining equations,

$$P_o = (A_{Fe} A_w) \times (B_s J) \times \frac{n}{n+1} (s_f w_f G\, k_f) \times 4f \times 10^{-8} \qquad (7)$$

Appendix II. Method of Rating

For purposes of preparing this design information the magnetic amplifier rating was defined in the following manner: For the impedance limited case the rating is taken with impedance match, while in the thermally limited case the rating is taken at a temperature rise of 55 C. Resistive loading is used in both cases with the rated point determined to meet the geometry of Fig. 3, which shows the rated point so placed that the output is down 20% when the signal is moved halfway to cut-off. This places the point of rating beyond the knee of the characteristic, representing a usable choice for maximum output. For the resistance-limited case the rating point is determined graphically from Fig. 3. In the thermally limited case the load is adjusted to place the thermal limit at the one-per-unit output

of Fig. 3. The method described to define the rating is one (out of many other possible ones) which happened to be useful in preparing the design material.

Appendix III. Nomenclature

A_{Fe} = cross-sectional area of iron (net), square inches
B_s = saturation flux density, gausses
D_p = dynamic power gain[11]
E = voltage, average
f = frequency, cps (cycles per second)
G = fraction of copper in gate winding, usually 0.8
I_G = gate current rms, amperes
I_o = average output current, amperes
J = current density, amperes per square inch
k_f = a form factor
K_{AT} = ampere-turn gain
N_G = gate turns per core
n = matching index, $n=R_L/R_G$
P_o = output power, see equation 2
R = resistance, ohms
s_f = stacking factor
w_f = winding factor
w/w = power gain in watts per watt
θ = temperature rise, C

Subscripts

G = gate
L = load
o = output

Magnetic-Amplifier Design

Part II—The Windings

R. E. ANDERSON
ASSOCIATE MEMBER AIEE

Synopsis: This development of a practical approach to the design of the toroidal magnetic amplifier is based on synthesizing the design from design charts, thus avoiding the necessity for having available detailed data from previous equipment. Starting with a known power supply frequency, together with a desired gain and time constant, the load voltage and current are utilized in determining the core. With the core specified, additional charts and techniques are presented for the winding layout design. The usual heat transfer and resistance computations serve as a check on the initial design synthesis, and these complete the design process. A straightforward and practical step-by-step design procedure is outlined. This paper, the second of two on the subject, is concerned with the winding layout and the completion of the design. Part I,[1] presented the design approach and the method of core determination. Thus, information is given making possible the practical and effective design of the magnetic amplifier having toroidal construction.

WIDESPREAD INTEREST in the use and application of the magnetic amplifier has led to the need for an effective and practical method for the design of this component. For the purpose of supplying information to meet this need, charts have been prepared and data collected which will permit the design of toroidal magnetic amplifiers without reference to previous designs. The engineering problem is treated in Part I, together with the design procedure, which is based on, first, determining the core product of window area times iron area by using power rating and, second, by laying out a winding design utilizing the chosen core. This paper continues the design technique by making the turns computation and by making the winding layout design. Techniques for verifying the design synthesis are outlined, together with a step-by-step design procedure to enable the reader to achieve a clear-cut solution to his design problem.

Continuation of the Design Technique

Having chosen a suitable core by any available means such as the method described in Part I, the design process may be continued by computing the number of turns required for the gate winding. If the power supply voltage is specified, equation 1 may be utilized in calculating the gate turns.

$$N_G=\frac{E\times10^8}{4.44fA_{Fe}B_s(2.54)^2} \tag{1}$$

On the other hand, if one is working in the resistance-limited region or if the load impedance specifies that the gate winding should meet a certain required resistance, equation 2 may be utilized in determining the number of gate turns.

$$N=\sqrt{\frac{R_GA_{Cu}}{\rho\ MLT}} \tag{2}$$

When equation 2 is used to determine the gate turns, the appropriate power supply voltage may be determined from equation 1. Since approximately 23% of the window area is allocated to copper, and since one normally allocates 80% of the copper space to the gate winding, the cross-sectional area of the gate-winding conductor may be computed. This is done by dividing the available area by the number of gate turns. Obviously, in making this computation the same space allocation should be applied as was used to determine the appropriate core. Having chosen the core, the turns, and the wire size, the designer may proceed to the winding design charts. These additional charts are used to complete the winding

---

Paper 58-39, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted September 18, 1957; made available for printing November 6, 1957.

R. E. Anderson is with the General Electric Company, Schenectady, N. Y.

The author wishes to thank Dr. H. F. Storm for his provident counseling and helpful guidance which were so essential to the preparation of this material. Thanks also go to the author's many colleagues at the General Electric Company who graciously supplied their design data on magnetic amplifiers which exhibited production successes.

layout and to compare design dimensions with winding machine capabilities.

Starting with the layer-turns chart, Fig. 1, the winding layout is begun by evaluating the number of turns in the first layer. This chart takes into account the fact that the lack of precision in a typical toroidal winding machine results in only 95% of the inner perimeter being used for winding. In the preparation of the chart it has been assumed that a standard single coating thickness of insulating enamel is used on wire sizes AWG *41* and smaller, while a standard double-coating thickness of insulating enamel is employed on wire of size AWG *40* and larger. For other insulation thicknesses the proper correction should be applied. With a precision winding, an indication of the turns in the first layer would completely define the winding geometry. Although this is not obvious, it arises from geometrical considerations which yield the fact that in a precision winding, each additional layer has a fixed number, Δ, fewer turns than the previous layer, as will be analyzed in Appendix I. This loss in turns per layer is independent of the relative hole-to-wire diameter and approaches $\Delta = 2\pi$ in a multilayer winding. Although in actual practice most winding machines do not build a precision winding, it is possible to express the actual random-wound coil in terms of an equivalent number of fictitious layers. Thus, by applying appropriate factors to the precision winding, it is possible to obtain an accurate expression for practical winding machine performance. Since the layers may intermesh, rather than building on top of one another as assumed in a precision winding, the winding factor may approach unity. In Figs. 2 and 3 the intercept of the *X*-axis value of the number of turns in the first layer, with the *Y* value for the total number of turns in the winding, locates the design point. This point locates the number of layers in the winding and determines the approximate percentage of available copper which has been utilized by the windings. For windings having less than 360 degrees traverse, the number of turns in both the total winding and the first layer should be multiplied by 360 degrees divided by traverse degrees before entering the chart. With this multiplying technique the correct number of layers and correct space allocation may be read directly. Knowing the number of layers permits the evaluation of coil build, mean length of turn, and winding resistance in the usual manner as given by equations 3, 4, and 5.

$$t_w = \frac{L \times D_c}{0.95} \tag{3}$$

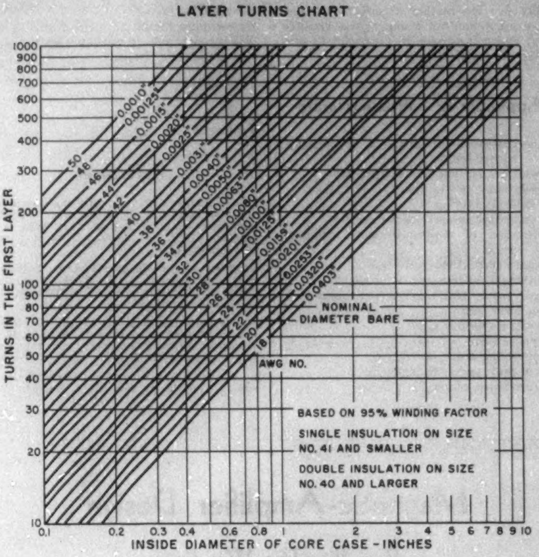

Fig. 1. Layer turns chart

$$MLT = 2[(t_s + t_t + t_w/2)\pi + h + F] \tag{4}$$

$$R = \rho \times \frac{MLT \times N}{12{,}000} \tag{5}$$

As a final check on the design geometry, the hole determination charts, Figs. 4 and 5, may be used. These charts, based on the same space allocations and wire insulation previously summarized, are used to estimate the hole remaining in the toroid after winding.

The intersection of the desired number of layers line with the chosen wire-size line in the rectangular portion of the chart represents the starting point for using these graphs. From this point one follows the rectilinear co-ordinates leftward to the triangular portion of the chart. By following the triangular coordinates in a downward and leftward direction to the intersection of the appropriate line for hole diameter before winding, the design point may be located. The scale on the left-hand side opposite the design point shows the hole remaining after winding while typical space allocation boundaries are shown for reference. The hole dimensions may be compared with the various winding machine capabilities shown in Table I. This table of winding machine data gives dimension limits and appropriate wire sizes for some of the commercially available toroidal winders.

After the gate winding has been laid out, the design proceeds to the control winding. The control turns are chosen to produce a specified current gain or to achieve a specified winding resistance. Probably the best way to determine the necessary number of turns for the control winding is to use data obtained from a core-testing equipment.[2] However, if such information is not available, a theoretical equation or a modification of this equation, which has been given by Storm,[3] may be used as shown in equation 6:

$$N_c I_c = \frac{H_c l_{Fe}}{0.4\pi} \tag{6}$$

Once the control turns have been chosen from core test data, from equation 2 or from equation 6, and with the available copper area known, the winding layout proceeds by the same steps previously discussed for the gate winding.

This process completes the design synthesis and design calculations. Nevertheless, it is advisable to check these computations to be sure that the design fully satisfies the needs and specifications involved. If the design is resistance-limited, i.e., comes from the lower left-hand portion of the core determination chart, Fig. 1 of Part I, the condition of impedance matching may be checked by a comparison between the calculated winding resistance plus rectifier forward drop against the actual load impedance. On the other hand, if the design is in the thermally limited region the use of Fig. 1 of Part I establishes the approximate heat-dissipating capacity; for a more accurate calculation the entire design rating may be checked by using the heat transfer information given in references 4 through 7. Needless to say, the actual winding space should be compared with the capabilities of the winding machines available for the job. The design process just described in detail is summarized in step-by-step form as shown in Table II.

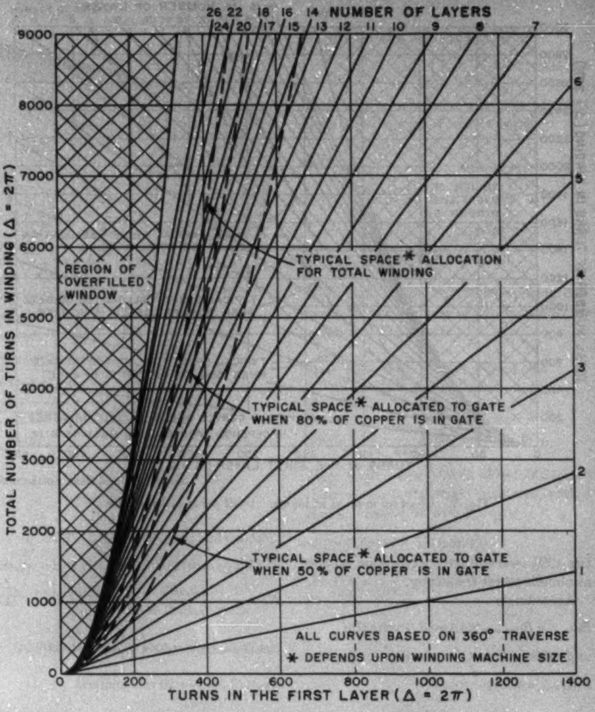

Fig. 2. Chart for number of layers: large cores or small wire

Design Example

As an example, consider the design of a center-tap full-wave single-ended magnetic amplifier to meet the following performance goals:

Power output (rated point; see Fig. 3, Part I): 14.5 va (volt-amperes), at room temperature with nominal voltage and frequency.

Load: 52.5 ohms resistive.

Power frequency: 60 cps (cycles per second) ±5%.

Maximum signal current: 5.5 milliamperes.

Design objective: high dynamic power gain with reasonable weight and size.

With these specifications as the starting point, the design may be calculated by following the steps given in Table VII of Part I, and Table II of the present paper. Accordingly, starting with Table VII, Part I, convert the minimum frequency to kilocycles:

Step I-*A*

$$f=\frac{57}{1,000}=0.057 \text{ kc}$$

With the specified 10% overvoltage, the maximum output becomes 14.5 $(1.1)^2$ = 17.6 va.

Step I-*B*

$$\text{output/kc}=\frac{17.6}{0.057}=308 \text{ va/kc}$$

Step I-*C:* From Fig. 1, Part I, size = 3.90 kilogausses × inches^4

Step I-*D:* To meet the design objective of high dynamic power gain would imply a permalloy type of core material while the size and weight objective could best be met by a silicon steel. A reasonable compromise between these materials (50% nickel, 50% iron core) will be chosen to approach both objectives. The thickness suitability depends upon the power frequency; for this example, at 60 cps, 4-mil or thinner tape may be used. For instance, in the following calculations consider 2-mil tape thickness.

Step I-*E:* From Table V, item 1, Part I, B = 14.5 kilogausses.

Step I-*F:* Determine the net quartic volume as

$$NQV=\frac{3.90}{14.5}=0.269 \text{ in}^4$$

Step I-*G:* From Table VI, Part I, s_f = 0.8.

Step I-*H:* Now the gross quartic volume may be determined:

$$GQV=\frac{NQV}{s_f}=\frac{0.269}{0.8}=0.336 \text{ in}^4$$

Step I-*I:* To obtain the high dynamic power gain objective, allocate most, e.g., 99%, of the copper space to the gate. Then

$$GQV_a=\frac{80}{99}\times 0.3362=0.2717 \text{ in}^4$$

Step I-*J:* From Table II, Part I, choose item 118.

Step II-*A:* First determine the appropriate line voltage

$$V_{\text{load}}=\sqrt{PR_L}=\sqrt{14.5\times 52.5}=27.6 \text{ volts d-c nominal}$$

With this nominal load voltage, the appropriate line voltage may be obtained by taking into consideration the gate-winding resistance (see Appendix II), the after-saturation inductance, and the form factor.

$$V_{\text{line}}=27.6\times 1.22\times\frac{1}{0.875}\times 1.11=42.7 \text{ volts rms nominal}$$

Of course, the turns are designed to handle

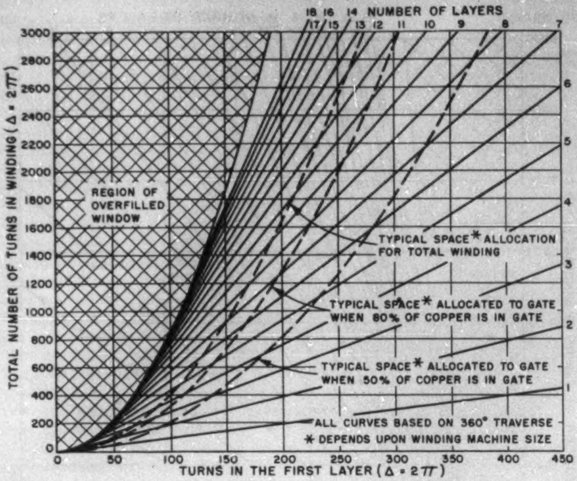

Fig. 3. Chart for number of layers: small cores or large wire

the 10% overvoltage specification at the minimum power frequency.

Accordingly

$E_{\text{line hi}} = E_{\text{line nom}} \times 1.1 = 47.0$ volts rms

and adding 1 volt for rectifier drop gives

$E_{\text{line max}} = 48.0$ volts rms

Then

$$N_G = \frac{E \times 10^8}{4.44 f A_{Fe} B_s (2.54)^2} \quad (1)$$

$$A_{Fe} = h \times F \times s_f = 1 \times \left(\frac{1}{4}\right) \times 0.8 = 0.200 \text{ in}^2$$

$$A_{Fe} \times (2.54)^2 = 1.29 \text{ centimeters}^2$$

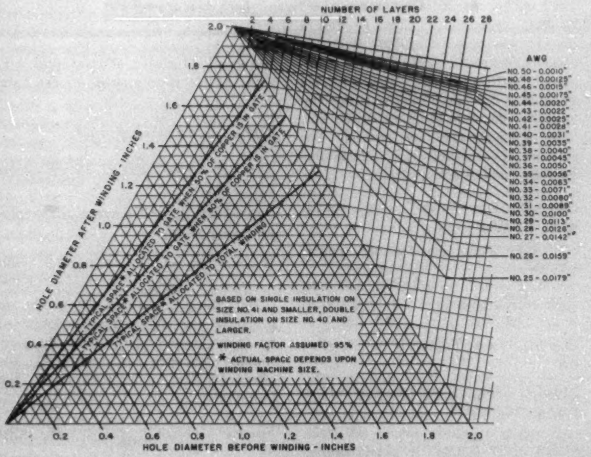

Fig. 4. Toroidal amplistat hole determination chart for small cores

$$\Phi = B_s A_{Fe} = 14{,}500 \times 1.29 = 18{,}710 \text{ maxwells}$$

$$N_G = \frac{48.0 \times 10^8}{4.44 \times 57 \times 18{,}710} = 1{,}014 \text{ turns}$$

Step II-*B*

$$A_{Cu} = A_w \times 0.225 = 1.0386 \times 0.225 = 0.234 \text{ in}^2$$

Step II-*C*

$$A_G = A_{Cu} \times 0.8 \times J_i = 0.234 \times 0.8 \times \frac{0.99}{0.8} = 0.231 \text{ in}^2$$

Step II-*D*

$$Ac_G = \frac{A_G}{N_G} = \frac{0.231}{1{,}014} = 228 \times 10^{-6} \text{ in}^2$$

Therefore try AWG *25* = 0.0179-inch diameter or 0.0206-inch insulated with a double coating of Formex* wire enamel.

$Ac_G = 252 \times 10^{-6}$ in² (actual)

$$I_L = \sqrt{\frac{P}{R}} = \sqrt{\frac{17.6}{52.5}} = 0.579 \text{ ampere d-c in load}$$

$$I_G \text{ per winding} = I_L k_f = 0.579 \times 0.86 = 0.498 \text{ ampere rms in gate}$$

$$J = \frac{I}{Ac_G} = \frac{0.498}{252 \times 10^{-6}} = 1{,}976 \text{ amperes/in}^2$$

Step III-*A*: From Fig. 1, at ID = 1.15, T_1 = 165 turns/layer.

Step III-*B*: Use standard insulation.

Step III-*C*: Use 360 degrees traverse.

Step III-*D*: From Fig. 3, at T_1 = 165 and N = 1,014, $L = 6.9 \cong 7$ layers.

Step III-*E*: Also note from Fig. 3 that available space is adequate.

Step IV-*A*: From Fig. 4 with ID = 1.15 and seven layers of AWG *25*, hole = 0.850 inch with gate winding applied before coil insulation is applied. Since the wraps of coil insulation must insulate the outer perimeter of the winding, the "bunching" on the inside will result in an insulation thickness of nearly 0.040 inch or a hole decrease of 0.080 inch.

Then, the hole after insulating will be 0.850 − 0.080 = 0.770 inch.

Step IV-*B*: Also note from Fig. 4 that available space is adequate.

Step IV-*C*: From Table I note that the following winding machines could be used for this job: Boesch standard, Harder, Micafil *RW-I*, or Rex *DB-2*.

$$MLT = 2\left[\left(t_s + t_w + t_i + \frac{t_G}{2}\right)\pi + A + F\right] \quad (4)$$

$$= 2[0.15\pi + 1.11 + 0.35] = 3.86 \text{ inches} = 0.322 \text{ feet}$$

$$\text{Length} = N\,MLT = 1{,}014 \times 0.322 = 326 \text{ feet per winding}$$

---

*Registered trade-mark, General Electric Company.

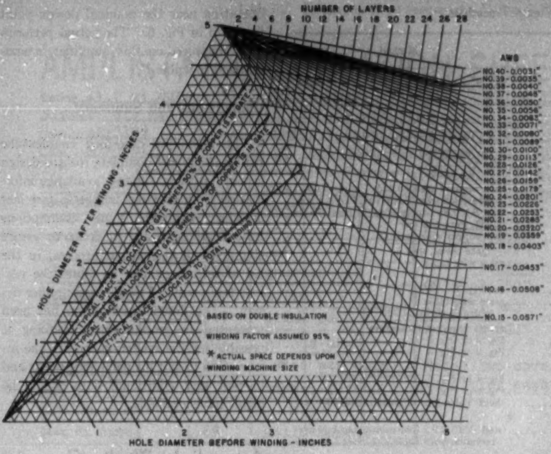

Fig. 5. Toroidal amplistat hole determination chart for large cores

$$R = \rho MLT = 33.0 \times 0.326 = 10.8 \text{ ohms} \quad (5)$$

$$\pm 6\%^{*} = 10.2 \text{ to } 11.4 \text{ ohms}$$

$$W = g\ MLT = 0.986 \times 0.326 = 0.322 \text{ pound}$$

$$R_{hot} = 1.19 \times 11.4 = 13.6 \text{ ohms maximum}$$

$$I^2 R_G = (0.498)^2 \times 13.6 = 3.4 \text{ watts}$$

Step V-*A*

$$A_C = A_{Cu} \times 0.2 \times J_s = 0.234 \times 0.2 \times \left(\frac{1-0.99}{0.2}\right) = 0.00234 \text{ in}^2$$

Step V-*B:* Determine the control turns from the dynamic coercive force

$$N_C = \frac{AT_c}{I_C}$$

$$AT_c = \frac{H_c l_{Fe}}{0.4\pi} = \frac{0.18 \times 11.99}{0.4\pi} = 1.72 \text{ ampere-turns} \quad (6)$$

$$N_C = \frac{1.72}{5.5 \times 10^{-3}} = 312 \text{ turns}$$

Note that at this point the exciting current, I_{ex}, for a-c test of the core may be computed as follows:

$$I_{ex} = \frac{AT_c}{N_G} = \frac{1.72}{1{,}014} = 1.69 \text{ milliamperes}$$

Step V-*C:*

$$Ac_C = \frac{A_C}{N_C} = \frac{0.00324}{312} = 7.49 \times 10^{-6} \text{ in}^2$$

Step V-*D*: Use AWG *40* = 0.0031-inch diameter or 0.0039-inch insulated with a double coating of wire enamel.

$$Ac_C = 7.5 \times 10^{-6} \text{ in}^2 \text{ (actual)}$$

$$J = \frac{I}{Ac_C} = \frac{5.5 \times 10^{-3}}{7.5 \times 10^{-6}} = 733 \text{ amperes/in}^2$$

---

* Each designer should use the tolerance appropriate to his particular manufacturing operation.

Table II. Step-by-Step Design Procedure

Steps	Method	
I. Core determination	See Part I of this paper	
II. Wire and turns computation		
A. Compute gate turns		
1. For fixed line voltage E, rms	$N=\frac{E\times 10^8}{4.44fA_{Fe}B_s(2.54)^2}$	(1)
2. For a specified gate resistance R_G	$N=\sqrt{\frac{R_C A_{Cu}}{\rho\ MLT}}$	(2)
B. Find total copper area	core window area $\times 0.225$: apply step J1 correction from Table VII, Part I, if any	
C. Find gate copper area	step B $\times 0.8$: apply step J4 from Table VII, Part I, if any	
D. Find gate conductor area	$\frac{\text{gate copper area, step C}}{\text{gate turns, step A}}$	
E. Use conductor area to find wire size	use a wire table	
III. Winding design		
A. Find turns in first layer	use Fig. 1	
B. Correct for unusual insulation (if used)	use a wire table	
C. Consider traverse if less than 360 degrees	$\frac{\text{multiply turns by 360}}{\text{actual traverse in degrees}}$	
D. Find the number of layers	Fig. 2 or Fig. 3	
E. Check space utilization	Fig. 2 or Fig. 3	
IV. Design checks		
A. Find winding hole	Fig. 4 or Fig. 5	
B. Check space utilization	Fig. 4 or Fig. 5	
C. Compare with winding machine capabilities	check Table I or references 8 and 9	
V. Control windings		
A. Find control copper area	(step IIB) $\times 0.2$ (one minus step I-J4 corrections, from Table VII, Part I, if any)	
B. Choose turns		
1. For fixed control current	$N_C=\frac{H_c l_{Fe}}{0.4\pi I_C}$	(6)
2. For specified control winding resistance R_C	$N_C=\sqrt{\frac{R_C A_{Cu}}{\rho\ MLT}}$	(2)
C. Find control conductor area	$\frac{\text{control copper area } A}{\text{control turns } B}$	
D. Use conductor area to find wire size	use a wire table	
E. Proceed with winding design	see step III	
F. Repeat design checks for control winding	see step IV	
VI. Check heat transfer or impedance matching	See references 4 through 7	

Step V-*E:* From Fig. 1, with ID = 0.77 inch and AWG *40*, $T_1 = 590$ turns per layer. Thus this winding could be wound in less than one layer. Frequently, however, it is desirable to leave some of the traverse for other windings; for example, bias, feedback, stabilizing, or extra control windings. Methods for handling such a situation will follow by assuming that the control winding traverse is limited to 50 degrees.

Then, the turns in the first layer T_1 are

$$T_1 = 590\times\frac{50}{360} = 82 \text{ turns}$$

For finding layers use Fig. 2 with $82 \times 360/50 = 590$ turns per layer and with $312\times 360/50 = 2246$ turns. Thus, $L = 3.9 \cong 4$ layers and, from Fig. 4, the hole = 0.73 inch.

Note that now the total space utilization may be checked by locating the intercept of this final hole after winding, 0.73 inch, with the initial case ID of 1.15 inch. At this point it is seen that typical space utilization has been achieved.

Continuing with the control winding calculations:

$$MLT = 2\left[\left(t_s+t_w+t_1+\frac{t_C}{2}\right)\pi + A + F\right] \quad (4)$$

$$= 2[0.21\pi + 1.46] = 4.24 \text{ inches} = 0.353 \text{ foot}$$

$$\text{Length} = N\ MLT = 312\times 0.353 = 110.2 \text{ feet}$$

$$R = \mathrm{P}\ MLT = 1101\times 0.1102 = 121.3 \text{ ohms}$$

$$W = g\ MLT = 0.0298\times 0.1102 = 0.00328 \text{ pound}$$

$$I^2R = (5.5\times 10^{-3})^2\times 121.3\times 1.19\times 1.18 = 5.15\times 10^{-3} \text{ watts}$$

These design calculations are summarized in the calculation sheet shown in Table III. Of course, a heat transfer check similar to that used in transformer design should be undertaken at this point as a final step. With such information available from the literature and with the actual result depending upon the particular mechanical construction used, the heat transfer calculations will not be shown. It may be mentioned that in a construction where the two cores are mounted on top of one another so that approximately half of each surface is available for cooling, the hot spot rise will be nearly 55 degrees centigrade at rated output.

A center-tapped full-wave self-saturating magnetic amplifier was constructed in accordance with these calculations. The control characteristic of this amplifier operating near the nominal design point is shown in Fig. 6. The actual performance measured on this amplifier is summarized in Table IV.

Conclusions and Summary

The technique described enables the reader to prepare complete reactor design layouts without having available information from previous magnetic amplifier designs. Although some assumptions have been necessary in order to assure simplicity of the design process, in the list of references may be found the various fine points of magnetic amplifier design. The design information has been presented in graphic form, making it possible for the reader to modify the information to suit his particular needs and to plot any additional data which he might have available.

Appendix I. Winding Geometry

The turns in a layer of mean diameter D is given by

$$T = \frac{\pi D}{D_c} \quad (7)$$

Now consider the difference Δ in turns per layer found in adjacent layers

$$\Delta = T_{n-1} - T_n \quad (8)$$

$$\Delta = \frac{\pi D_{n-1}}{D_c} - \frac{\pi D_n}{D_c} \quad (9)$$

However, from Fig. 7,

$$D_n = (D_{n-1} - 2D_c) \quad (10)$$

Then, from equations 9 and 10,

$$\Delta = \frac{\pi(D_{n-1} - D_{n-1} + 2D_c)}{D_c} \quad (11)$$

$$\Delta = 2\pi \quad (12)$$

Equation 12 indicates that in an ideal precision toroidal winding each layer has 2π fewer turns than the previous layer. Of course, in actual practice, Δ must be an integer number, e.g., 6 or 7, and the 2π value is achieved only by averaging over a number of layers.

Since Δ is constant and independent of the relative layer and wire diameters, equation 12, it is possible to determine the number of layers. For a winding of N turns with T_1 turns in the first layer, the arithmetic progression equation[10] is

$$N = \frac{L}{2}[2T_1 + (1-L)\Delta] \quad (13)$$

by algebra, and ignoring the extraneous root, the practical solution is

$$L = \left(\frac{T_1}{\Delta}+\frac{1}{2}\right) - \sqrt{\left(\frac{T_1}{\Delta}+\frac{1}{2}\right)^2 - \frac{2N}{\Delta}} \quad (14)$$

Thus equation 14 gives the number of layers in a precision wound toroid. By applying

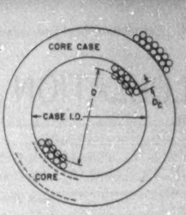

Fig. 7. Winding geometry

the appropriate winding factors to the first layer turns T_1 and to the turns difference Δ, equation 14 may be made to represent the actual performance of any winding machine. Although in practice T_1 is always slightly reduced by this winding factor, the fact that most toroidal winding machines do not build successive layers on top of the previous layer, but have a tendency to drop conductors in some of the grooves between turns of the previous layer, also makes Δ slightly reduced in practice. (Note that in a toroidal winding with layer insulation, Δ would always be greater than 2π.) For these reasons the net effect of the winding factors may become quite negligible.

Appendix II. Matching Index

As an aid in estimating $R_o/R_L=1+R_G/R_L$, one may use the similarity laws published by Storm,[3] chapter 16. These relationships are

$$\frac{P_{L,m}}{P_{L,m_1}}=\left(\frac{d}{d_1}\right)^3\left[2\left(\frac{d}{d_1}\right)^{3/2}-1\right] \tag{15}$$

from which the ratio d/d_1 may be estimated. Then

$$n=\left[2\left(\frac{d}{d_1}\right)^{3/2}-1\right]=\frac{R_L}{R_G} \tag{16}$$

and hence

$$\frac{R_o}{R_L}=1+\frac{1}{n} \tag{17}$$

Of course, these equations are based on dimension ratios, such as ID/OD, h/F, etc., which do not change with size. Furthermore, it is implied that the heat transfer geometry be independent of size. Actually in small units and large reactors mounted separately the total reactor surface is useful in cooling. On the other hand, when two medium size reactors, which comprise one magnetic amplifier, are placed on top of one another for mounting or encapsulation, only half the reactor surface may dissipate heat. Thus, in practice, the actual heat transfer geometry may change with size. In the latter case equation 17 may approach

$$\frac{R_o}{R_L}=1+\frac{1}{2n} \tag{18}$$

where n is determined from equations 15 and 16 with, as a base, a reactor where the entire surface is available for heat transfer. For instance, the base sizes are approximately 3.6 va at 60 cps and 0.14 va at 400 cps for typical toroidal designs with 55 degrees centigrade rise. (Note that the base reactor is of such size as to be both resistive and thermally limited. Thus the base reactor represents the boundary case where resistive limited and thermally limited meet.)

Appendix III. Nomenclature

A_C=area of copper allocated to control, in
A_{CC}=cross-sectional area of control conductor, in^2
A_{CG}=cross-sectional area of gate conductor, in^2
A_{Cu}=total copper area, in^2
A_{Fe}=cross-sectional area of iron, net, in^2
A_G=area of copper allocated to gate, in^2
AT_c=dynamic coercive magnetomotive force, oersteds
A_w=cross-sectional area of window, in^2
B_s=saturation flux density, gausses
d=representative dimension of a magnetic amplifier
d_1=representative dimension of base magnetic amplifier of such size as to be both resistive and thermally limited
D=mean inside diameter of a layer of winding
D_c=diameter of conductor, inches
E=effective line voltage, rms volts
f=frequency, cps
F=core stack, (OD—ID)/2 inches
g=weight per unit length of conductor material, pounds per 1,000 feet
GQV=gross quartic volume=NQV/s_f, in^4
GQV_a=gross quartic volume after modification, in^4
h=core height or tape width, inches
H_c=coercive magnetomotive force, oersteds
I_C=average control current, amperes
ID=inside diameter, inches
I_{ex}=a-c exciting current, amperes
I_G=gate-winding current, amperes
I_L=load current, d-c amperes
J=current density, amperes/in^2
k_f=appropriate form factor, no units
l_{Fe}=mean length of magnetic circuit, centimeters

A New Method of Frequency Error Correction in Carrier Systems

B. R. STACHIEWICZ
MEMBER AIEE

THE PROBLEM of frequency error correction in carrier systems has become more and more important in recent years. Not long ago, the use of free-running oscillators at both terminals of the system was considered satisfactory in many cases. Today an end-to-end stability of ±1 cycle is normally required.

Also, when multichannel systems grouped in a higher frequency range are used, several steps of modulation may be needed to position a channel in the proper place in the final spectrum. Since each step of modulation requires a carrier, any deviation in this carrier frequency will cause an error in the transmitted signals.

It was therefore found necessary to minimize these errors as far as possible. One of the methods presently in use consists in generating all carrier frequencies required at a terminal from a single oscillator, by harmonic or subharmonic generation of required tones. At the distant terminal, a similar arrangement is used to provide demodulating frequencies. It is evident that the frequency stability of over-all systems depends on the stability of master oscillators at the terminals. These are normally crystal oscillators enclosed in ovens to ensure constant temperature operation. Depending on the performance of the quartz crystals and ovens, adequate stability may be obtained in such systems.

However, when the system is to operate over facilities and media that may in themselves introduce changes in frequency of the signals, the foregoing method cannot correct for such errors.

There are many instances of such operation. In cable and open-wire systems, the so-called frequency-frogging repeaters are often used. Frequency frogging consists in inverting the arriving band of frequencies and transposing it into a different portion of the spectrum. In this manner equalization of losses introduced in the cable or open wire is achieved. The inversion is performed by modulation at the repeater and is shown in Fig. 1. It is apparent from this that, in a system operating through a number of frogging repeaters, a frequency error may be introduced at each repeater because of the deviation of carrier oscillator frequency from its nominal value.

It is conceivable that repeater oscillators could be enclosed in ovens to improve their frequency stability, but from a practical point of view the use of ovens at the repeaters may be impossible because of power consumption requirements and other difficulties. A good example of this is a transistorized repeater, which is powered from a distant location over the wire pairs.

The power required for the oven could possibly exceed that required for the transistor circuitry, and could also make it impossible to feed more than one or two repeaters from a distant point. The use of an oven at the repeaters is therefore not considered a satisfactory solution to this problem.

In radio communications frequency errors may also be introduced in the transmission medium. A notable example of this is the case of ground-to-air or air-to-air communication, where the receiver may be located in fast-flying aircraft.

With modern jet-propelled planes, an appreciable change in frequency may occur as the result of Doppler effect. In single side-band transmission one method of eliminating such a shift consists in transmitting the carrier frequency adjacent to the speech spectrum and using it for demodulation at the receiver. This method, however, has the disadvantage that transmission of many carriers may result in overloading the radio equipment.

Paper 58-239, recommended by the AIEE Wire Communications Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted April 8, 1957; made available for printing November 29, 1957.

B. R. Stachiewicz is with the Federal Telecommunication Laboratories, Palo Alto, Calif.

The frequency-correcting circuit described has been successfully tested in the laboratory. The author wishes to acknowledge the work of O. Jorgensen, of the Stromberg-Carlson Company, who was responsible for the tests performed.

Fig. 1. Frequency-frogging repeater

Group carriers, used in single side-band modulation, fall outside the transmitted band of their particular group and may interfere with other groups if transmitted.

This discussion will be confined to wire-line communications systems but it should be kept in mind that the principles are also valid for other methods of transmission.

The method of frequency error correction to be described was originally developed for a 2-wire 12-channel system. This system consists of three 4-channel groups, each group occupying 36-kc of spectrum. In this discussion only the group will be considered which transmits in the frequency band of 120 to 136 kc and receives in the band of 140 to 156 kc, or vice versa. At each repeater frequency frogging is achieved by modulation of a 276-kc carrier. The basic four channels occupy the spectrum from 12 to 28 kc. A pilot frequency located in the middle of the group (20 kc) is continuously transmitted. The simplified schematic for the complete system showing nominal frequencies is represented in Fig. 2. A 4-wire arrangement is shown in order to isolate the directions of transmission for the sake of clarity. Normally, such systems will operate on a 2-wire basis. To understand the operation of the frequency-correcting circuits to be described, it must be kept in mind that it is necessary to prevent frequency changes in the end-to-end transmission of a signal and, because the method for accomplishing this works on the principle of cancelling one error with another, carrier and pilot frequencies throughout the system will purposely contain frequency errors.

In the accompanying figures, the exact frequencies of both the signal and the pilot are given, although it is apparent that, because the pilot tone is located in the middle of the signal band, it will undergo the same changes in frequency as any other signal in the band. The reason for showing both tones is that carrier frequencies are derived from the pilot tone, and consequently a change in the frequency of this tone will result in a change of carrier frequency.

Only the common equipment portion of the terminals is shown in the figures. Frequency translation to and from the voice range is accomplished in the channel units and does not affect the discussion. Frequency errors that may occur in channel modulators are negligible, compared to those introduced at the repeaters.

It is assumed throughout this discussion that frequency frogging at the repeater is accomplished by lower side-band modulation. This is always true, because inversion of the band is required for slope correction.

Fig. 3. Unidirectional frequency correction

Theory

Unidirectional Frequency Correction

Assume that frequency f_p is generated by a stable oscillator and is used as a pilot in the system shown; see Fig. 3. Two stages of modulation are shown, in one of which the carrier frequency contains an error a. This one stage may be throught of as representing an unlimited number of modulators with the total frequency error introduced in all of them being equal to a. The pilot frequency therefore emerges from the modulator as $(f_1-f_2+a+f_p)$ assuming lower sideband modulation. The frequency corrective network consists of two modulators and two filters forming a "bootstrap" circuit.

The arriving pilot frequency is picked off at the input to the corrector and passed to modulator B, in which it is combined with another frequency obtained from the output of modulator A. The combination of these two frequencies in modulator B produces the required carrier frequency for modulator A. As seen from Fig. 3, the output pick-off filter K is tuned to the difference between the nominal frequency of the incoming pilot and the carrier frequency. In this manner, the carrier frequency generated from the incoming and outgoing tones contains the error a which cancels the error of the same magnitude present in the incoming signal. The output from modulator A then contain no error. Due to the bootstrap nature of this circuit, the stability of the output frequency is determined by the accuracy and stability of filter K. If filter K is tuned slightly off the f_p frequency so that f_p+a predominates, the desired signal f_x will then contain an error frequency f_x+a. However, as will be shown later, this error will cancel out when the circuit is used for 2-way trans-

mission. It is thus apparent that errors introduced in any frequency f_x transmitted over this system will be corrected in the corrector; this is also shown in Fig. 3.

Practical Applications

For the sake of clarity, this method will now be applied to the 4-channel system operating in the frequency range of 120 to 136 kc, transmitting east to west, and 140 to 156 kc receiving from the west.

The east terminal modulation steps are as follows:

1. The 4-channel units in the voice range 0 to 4 kc are first modulated to a basic subgroup of 12 to 28 kc.
2. This subgroup then modulates a 148-kc carrier to produce the output band of 120 to 136 kc. This step is represented by modulator 1 of Fig. 3.
3. The pilot frequency represented by f_p in Fig. 3 is set at 20 kc and consequently after modulation it becomes 128 kc.
4. The frogging frequency of the repeater is 276 kc and the repeater may be represented by modulator 2. An error a is assumed in this frequency.
5. The receiving terminal is represented by the corrective circuit.

This system is shown in Fig. 4, where the configuration of the W-E (west-east) circuit is identical with that of Fig. 3.

To achieve cancellation of frequency errors in the oppostie E-W (east-west) direction of transmission, the carrier frequency used in modulator 5 is purposely shifted by a cycles, which is the same error as that occurring in the repeater.

Inspection of Fig. 4 indicates that error introduced at the repeater will be canceled by the time the west terminal is reached.

In Fig. 5 the circuitry used for both directions of transmission shown in Fig. 4 was combined. It will be noted that modulators 4 and 5 of Fig. 4 were com-

bined into one, and a 20-kc band-pass filter was introduced between the transmitting and receiving pairs at the east terminal. At the west terminal, a 128-kc oscillator was introduced to provide the receiving carrier and the outgoing pilot frequencies.

Analysis of Circuit Properties

The circuit of Fig. 5 shows very interesting error-canceling properties which will now be examined. Four conditions of interest are:

1. Only repeater frequency drifts.
2. Only 128-kc oscillator frequency drifts.
3. Only 20-kc pilot pick-off filter tuning changes.
4. All the foregoing deviations occur simultaneously.

A detailed analysis of circuit performance under these conditions is given later in this section, following a short summary.

In each case frequency correction is achieved in a demodulator where the carrier and the incoming signal contain the same error. The equation for demodulation is $(f_c+a)-(f_x+a)=f_c-f_x$, where (f_c+a) is the carrier frequency and (f_x+a) is the incoming signal. To make certain that the carrier contains the same error as the signal, the carrier frequency is derived directly from the signal.

The case of repeater frequency drift is shown in Fig. 5. A tone of 15 kc is injected at the west and east terminals. It is apparent from the figure that error cancellation results in both directions of transmission. This is true for any number of frogging repeaters. It should be noted that only the carrier frequencies at the east terminal contain frequency errors.

When only the 128-kc oscillator at the west terminal drifts, the resulting frequency error is reproduced in the opposite, E-W, direction of transmission, and

Fig. 8. All errors combined

cancellation occurs at both terminals, as shown in Fig. 6. All carrier frequencies at both terminals, and pilots in both directions of transmission, contain frequency errors.

If the tuning of the 20-kc pick-off filter changes, because of temperature or other effects, cancellation of errors still results, as shown in Fig. 7. It should be observed that only carrier frequencies affecting the W-E direction of transmission contain frequency errors and only the E-W pilot is in error.

Fig. 8 shows what happens when the repeater frequency, the west terminal 128-kc oscillator and the 20-kc pick-off filter are off frequency at the same time. It will be noted that, although all pilots and all carriers in the system contain frequency errors, the speech tones will be transmitted end to end without frequency deviations. The permissible magnitude of oscillator drift is limited only by the bandwidth of the carrier pick-off filters at the terminals, which in turn depends on the permissible interference between the carrier and the adjacent speech channels.

To analyze the error-correcting properties of the circuits shown in Figs. 5 through 8, it is necessary to consider the pilot and carriers separately from the speech tones. In the figures, the frequenices of a typical speech tone are represented by 15 kc and are shown on the outside of the diagrams, i.e., above the line for the W-E direction and below the line for the E-W direction. Frequencies of the pilot tone (128 kc) and the carrier frequencies are shown inside the diagram.

The pilot tone generated by the 128-kc oscillator at the west terminal is transmitted toward the east; see Fig. 5. At the repeater, this tone is modulated by the repeater frequency of (276 kc$+a$) where a is the frequency deviation from nominal. Assuming lower side-band modulation, the pilot tone emerges from the modulator as $(276+a)-128=148$ kc$+a$. The pilot frequency now contains the error a.

Upon arrival at the east terminal, the pilot frequency is selected by a band-pass filter and used as the carrier frequency for the transmitting modulator in the E-W direction. This frequency still contains the error a and consequently any signal transmitted in the E-W direction will emerge from the transmitting modulator shifted in frequency by a cycles. Considering again the receiving portion of the east terminal, it is apparent that the incoming pilot tone will be demodulated in the receiving demodulator. To eliminate the error of a cycles contained in the pilot tone, the carrier frequency actuating the demodulator must also contain an identical error of a cycle. Because of the bootstrap circuitry it is difficult to describe the generation of this carrier without reference to Fig. 5. Assuming for the moment that the carrier frequency is (128 kc$+a$), the pilot will demodulate into $(148+a)-(128+a)=20$ kc, and the error will be cancelled. The 20-kc tone is then picked off by the band-pass filter and retransmitted in the E-W direction.

However, as has been mentioned, the carrier frequency of the E-W transmitting modulator, which was derived from the W-E pilot, contains the error a. The retransmitted pilot tone will therefore emerge from the transmitting modulator containing the error a in accordance with the following translation: $(148+a)-20=$ (128 kc$+a$).

It may immediately be seen that this frequency is the same as the one previously assumed for the W-E demodulator carrier and can therefore be used directly to actuate this demodulator, thus completing the closed loop circuit.

Considering transmission in the E-W direction, the pilot frequency containing an error a modulates the repeater carrier which also contains the same error. The lower side-band product of this modulation therefore does not contain any error. (276 kc$+a$)$-$(128 kc$+a$)$=148$ kc.

From this consideration of the pilot and carrier frequences, it may be seen that any tone transmitted through the system (represented by 15 kc) will emerge from the receiving demodulator at exactly the same frequency as that at which it entered the transmitting modulator. This is true regardless of any shifts in frequency which may occur within the system.

The frequencies of the system when the pilot generator drifts in frequency are analyzed in Fig. 6; and when the tuning of the pilot pick-off filter at the east terminal changes, in Fig. 7. The analysis is similar as in the case of Fig. 5. There is, however, one important feature that must be clearly realized: It is entirely possible for the pilot tone to contain a frequency error at the output of the receiving demodulator while the speech tone (15 kc) contains no error.

The purpose of the circuitry described is to eliminate frequency errors from transmitted speech signals only, and it is not suggested that pilot tone will contain no error at the output, although this will be the case in many instances.

An illustration of such a condition is given in Fig. 8. Here all conceivable errors occur simultaneously. An analysis of this condition will reveal the fact that during transmission the pilot frequency contains frequency errors different from those affecting the 15-kc signal. The net effect is that the speech spectrum is displaced relative to the pilot tone by an error e. In the end, however, all errors affecting the 15-kc signal cancel out.

Conclusions

The limitation of the frequency-correcting system described consists in the fact that the pilot frequency in one direction of transmission is the same as the carrier frequency required for the opposite direction. The principle may be applied, however, to a more general case by the use of additional modulators in the frequency-correcting circuits.

It should be noted that group oscillators were completely eliminated from one terminal, and that only one oscillator is required at the other terminal. Since the stability of this oscillator is not critical, no special precautions are necessary.

Oscillators in the repeaters need not be stabilized, and the number of repeaters in the system is limited only by the total allowable deviation from nominal frequencies, which depends on the selectivity and bandwidth of various band-pass filters used. It should be mentioned that errors introduced in the repeaters will tend to cancel each other if frequencies of the oscillators in the repeaters drift in the same direction in all units.

In general, it is believed that the circuitry described will permit simplification and cost reduction of equipment. In addition, many further possibilities, outside the scope of this paper, are apparent in its use.

An Experimental Study of Magnetic Materials for Use in Ultrahigh-Temperature Electronic Transformers

H. B. HARMS
ASSOCIATE MEMBER AIEE

THE VERY HIGH temperatures that are expected to be encountered in aircraft and missiles are presenting unusual problems to the designers of electronic equipment and components. Two solutions that have been suggested are the following: 1. that more cooling capacity be introduced to maintain the equipment at a safe maximum operating temperature, and 2. the use of parts and processes that are inherently temperature tolerant over a wide temperature range. If the latter approach is taken, the component designer must make a major development contribution to extend successfully the ambient temperature rating of his device from a present-day 200 C (degrees centigrade) maximum to a value which is expected to be as high as 500 C.

Through contract No. *AF33(616)-3623* the Air Force is sponsoring the development of electronic power transformers which will be capable of withstanding a 500 C ambient temperature as well as the other adverse environments to which military equipment is normally exposed. One important material used in transformers and for which the designer requires exact knowledge is the iron core. It is known to have temperature-dependent properties. The purpose of this paper is to describe the experimental work performed as one phase of the development to determine quantitatively the effect of temperature on magnetic materials. Properties pertinent to power transformers are core loss, excitation, and incremental permeability. These were measured on a grain-oriented silicon iron at several flux densities and at four different temperatures up to 550 C, to obtain basic data expected to be useful in the design of plate and filament transformers and reactors.

Materials Survey

Five general types of steels are known to retain their magnetic characteristics at temperatures as high as 600 C. These are low-carbon steel, powdered iron, silicon steel, grain-oriented silicon steel, and cobalt iron. Of these, grain-oriented silicon steel was selected for evaluation because of its well-known superior performance in normal commercial and military applications, its availability and low cost, and its long accumulated processing background. Although cobalt iron surpasses it in Curie temperature (740 C as opposed to 900 C) and in room temperature saturation flux density (15 kilogausses as opposed to 20 kilogausses), it is 20 times as costly as the grain-oriented silicon steel, and uncertain processing problems are assocated with it.

The complete designation of the silicon steel evaluated is *AISI-M6* grain-oriented $3\,^{1}/_{4}\%$ silicon steel. A 0.010-inch thickness was used because of the contemplated 400-cycle-per-second frequency application. The material was supplied in strip form with a thin film of high-temperature insulative coating on each side. It was then punched into the desired shape and given a standard 1,115 C pure dry hydrogen anneal.

Test Conditions

PROPERTIES MEASURED

Exciting current and core loss, fundamental indications of the condition of magnetic materials, were measured at 400-cycle-per-second frequency as a function of flux density at four different temperatures: 30, 250, 400, and 550 C. Measurements were made approximately 4 hours after exposure to the desired temperature. Data suitable for use in the design of reactors were also obtained at these four temperatures and at three a-c flux density values: 25, 1,000, and 5,000 gausses. Aging tests were made in addition to the short-time tests to determine the effect of exposure of the material to a 550 C temperature for 1,000 hours. The effect was measured by observing the core loss and excitation initially, at 300 hours, at 600 hours, and finally at 1,000 hours.

TEST SPECIMENS

The 0.010-inch grain-oriented strip material was punched into several sizes of *UI* and *EI* lamination shapes. These were then stacked into coils specially designed for each size. A stack height of approximately one and one-half times the leg width was used. The coils were of standard construction. The sheet and spool insulation was composed of mica paper, while a glass fiber was used for the wire insulation. The secondary was wound on first and the primary on top of it. The wire for the secondary in all samples was 0.0126-inch nickel-clad copper, while the aluminum wire of the largest diameter that could be fitted into the space available for the coil was used for the primary. In this way the coil copper losses were maintained at a negligible value. The leads were made long enough to pass through the test furnace door to eliminate junction-point problems. Six samples of each core size with their associated coils were evaluated. Representative specimens in place for the elevated temperature tests are shown in Fig. 1. The number of samples was reduced to two and to a single lamination size for the reactor design data tests. Lamination sizes for the core loss and excitation tests covered the width range for the major leg from 3/8 to $1^{1}/_{8}$ inches in 1/8-inch increments.

TEST PROCEDURE

Core loss and exciting current data were obtained with the use of the circuit in Fig. 2. The flux density was controlled with the input voltage. The induced voltage from which the flux density was calculated was measured with a calibrated rectifier volt-meter placed across the secondary leads. At each flux density setting the input current, watts, and output voltage were read. Six to eight flux density settings were used for each core over a 20- to 110-kiloline-per-square-inch range. Data obtained in this manner were analyzed and plotted as core loss in watts per pound, and excitation in ampere-turns per inch as a function of flux density and temperature.

Paper 58-209, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted October 14, 1957; made available for printing November 25, 1957.

H. B. HARMS is with the General Electric Company, Fort Wayne, Ind.

The author wishes to acknowledge the support of the work reported in this paper by Air Force Contract No. *AF33(616)-3623* through its project engineer, J. F. Rippin, Jr.; the design of the test specimens and the performance of the tests by R. S. Russell; and the counsel and guidance of D. B. Bovey.

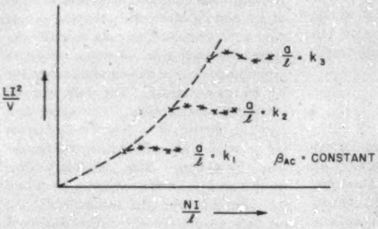

Fig. 3 (left). Typical reactor design curve

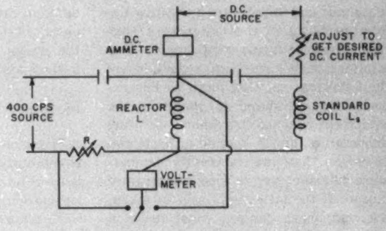

Fig. 4 (right). Test circuit for reactor design data tests

Data suitable for the design of reactors are usually plotted as LI^2/V versus NI/l[1] where

L = inductance, henrys
I = direct current flowing in the reactor circuit, amperes
V = core volume, cubic centimeters
N = number of reactor coil turns
l = mean length of magnetic circuit, centimeters

Two parameters are a-c flux density and the ratio of air gap to mean length of magnetic circuit a/l, where a = total air-gap length, in centimeters.

Data are obtained for a given air-gap ratio and a-c flux density by varying the direct current. The larger the air-gap ratio, the higher the direct current (NI/l) required to reach a maximum LI^2/V. Fig. 3 illustrates the type of raw data obtained. The envelope of the individual curves is then drawn (the dashed curve in Fig. 3) and transverse marks placed on it at the tangent points to locate specific a/l values. This latter curve is used for the design of reactors.

The circuit used to obtain the reactor design data is shown in Fig. 4. In this circuit R is adjusted to give equal voltage drops across itself and L. The alternating voltage and direct current are held constant during this operation. Under these conditions the inductance L is calculated from

$$L = \frac{L_s R}{2\pi f L_s - R}$$

where

L = unknown inductance, henrys
L_s = known air core inductance, henrys
f = a-c applied frequency
R = measured value of resistance R in Fig. 4, ohms

With L now known, the curves in Fig. 3 may be plotted.

Data Analysis

CORE LOSS AND EXCITATION DATA

The raw data were statistically analyzed with the aid of a digital computer program. By means of this program they were first converted to watts per pound, ampere-turns, and flux density. A curve of best fit for a given core size and property was then determined by trying successively higher order polynomial equations until the 5% point of the F distribution test could be satisfied. Flux density was used as the independent

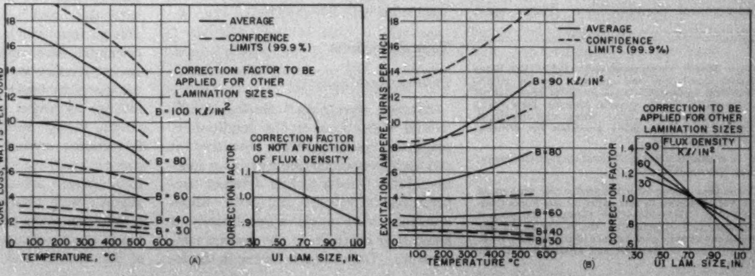

Fig. 5. Core loss and excitation as functions of temperature and flux density for UI shaped laminations. Laminations were stacked in inter-leaved alternate groups - of - four arrangement

A—Core loss
B—Excitation

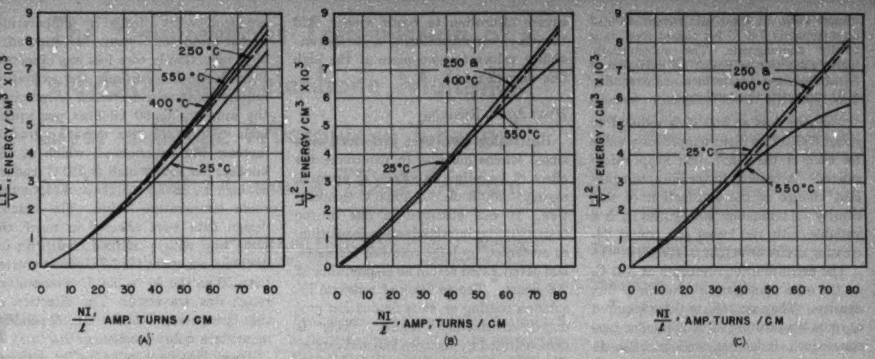

Fig. 6. Reactor design curves for various a-c flux densities: A, B, and C: 25, 1,000, and 5,000 gausses respectively

variable. Confidence limits at 99.9% were finally determined, and this and the average value were printed out at flux density points from 30 through 110 kilolines per square inch at intervals of 10 kilolines per square inch.

The core loss and excitation data as read from the computer program are plotted in Fig. 5 as a function of temperature with flux density as an adjustable parameter for particular *UI* lamination-shaped leg widths. The 3/4-inch width selected fitted approximately midway in the size range tested. Further analysis showed that data from the other lamination sizes were similar to these, although displaced in an orderly pattern depending on size and, in the case of the excitation, on the flux density as well. Simple correction factors therefore make the one set of data applicable for all the other sizes.

These correction factors, described in the foregoing, have been included in the curves of Fig. 5.

Reactor Design Data

These data were plotted according to the scheme illustrated in Fig. 3 for each of the two samples. The average envelope curve was then drawn for each a-c flux density and temperature condition. The analyzed data are plotted in Fig. 6(A) through (C). Each graph is for a different a-c flux density, while temperature is used for the parameter. The transverse gap ratio marks as used in Fig. 3 have been omitted, and replaced by a new curve, Fig. 7, of a/l versus NI/l which is a more accurate and a simpler way of determining the air gap required for a given direct current bias.

Data Interpretation

Core Loss and Excitation

The data reflect three major changes[1] that occur in magnetic steel when the temperature is increased. These are:

1. The electrical resistivity increases, giving rise to lower eddy currents and therefore a lower core loss.
2. Within the saturation limits of the material the permeability increases. The lower excitation values at an induction of approximately 50 kilolines per square inch and smaller, shown in Fig. 5(B), are a direct outcome.
3. The flux density value at which the material becomes saturated gradually de-

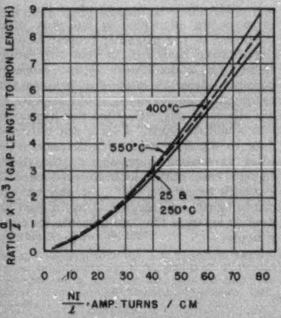

Fig. 7. Curves to determine gap length for reactor designs. Data applicable for design purposes for any a-c flux density up to 5,000 gausses

A—Core loss
B—Excitation

creases until, at the Curie temperature of approximately 740 C for silicon steel, it is totally nonmagnetic. The substantially higher excitation values at an induction of 50 kilolines per square inch and over, Fig. 5(B) emphasize this tendency.

The core loss at 550 C is reduced to about 60% of its room temperature value for each of the lamination shapes considered. According to the data, this percent change is not a function of flux density. Lamination size, however, is a variable with the losses per pound decreasing as size or weight is increased.

The excitation requirements at 550 C, on the other hand, are a function of flux density. They are 75% of those required at room temperature for a 30-kiloline-per-square-inch induction, and increase to approximately 200% at 100 kilolines per square inch. The flux density for which there is no change throughout the temperature range is estimated to be between 50 and 60 kilolines per square inch. Lamination size is a variable with the excitation decreasing as size or weight is increased.

REACTOR DESIGN DATA

Temperature and induction effects on the material are reflected in these data in the same manner as was observed with the core loss and excitation data. For a given temperature the permeability of the iron increases with flux density to a maximum until saturation starts setting in. Thereafter it slowly drops off to unity. Superimposed on this is the effect of temperature, which produces higher permeabilities at the low flux densities but causes saturation to occur sooner, and therefore, correspondingly lower permeability values to take place at the high flux densities.

HEAT AGING RESULTS

Heat aging tests were performed on a single lamination size to determine the effect of long-time exposure, of approximately 1,000 hours, to a 550 C temperature. It was observed in one of the tests that the interlamination insulation, as evidenced by large core loss increases, had deteriorated within an elapsed time of 200 hours. The addition of a second insulation coating on each lamination produced satisfactory results. This is demonstrated by the core loss and excitation data plotted in Fig. 8 at 30 and 550 C temperatures and at 24 and 1,000 hours' time exposure. The core loss for these particular conditions was essentially unaffected by the aging period. The excitation current, however, experienced small permanent changes amounting to as much as 15% at 550 C and 30% at room temperature.

Heat aging tests have indicated the very critical role that the interlamination insulation plays. The separation must be a positive one and free from any voids that will allow oxidation to progress between adjacent laminations.

Conclusions

The experimental work reported in this paper indicates that the magnetic properties of grain-oriented $3^{1}/_{4}$% silicon steel are significantly affected by temperature. In the 30 to 550 C range investigated, a 60% reduction in core loss was observed. For identical conditions the excitation requirements were decreased or remained the same up to 60 kilolines per square inch. Above this flux density a gradual increase was experienced, which at 100 kilolines per square inch at 550 C reached as high as 200% of the corresponding room temperature value. The reactor design data were affected in much the same way with a marked change in inductance occurring for NI/l values greater than 50 as the 30 to 550 C temperature range was traversed. The direction of this change was found to be dependent upon the a-c flux density.

These data have value for the designer who is confronted with the problem of designing small electronic power transformers and inductors for operation in a wide range of ambient temperatures. Possible revisions in his design practice that are a direct outcome of this knowledge include the use of lower operating flux densities, adjustment of the temperature rise to take into account the change and redistribution of the losses in both the core and coil, and a compromise on the gap setting in the case of an inductor application.

Discussion

M. Pasnak (U.S. Naval Ordnance Laboratory, Silver Spring, Md.): Current work at the U. S. Naval Ordnance Laboratory (to be published) on the effects of high temperatures on magnetic properties of core materials, generally confirms the author's interesting results. However, it is felt that there is need to elaborate upon the interpretation of his data pertaining to the decrease in core loss with increase in temperature. He attributes the decrease in core loss to an increase in electrical resistivity, which decreases the eddy current losses. Our data, obtained on 12 different core materials tested up to 800 C, indicate that the contribution of the hysteresis loss decrease is significantly greater than that of the eddy current loss. Therefore the decrease in the total core loss with increase in temperature should not be interpreted solely in terms of an electrical resistivity increase.

H. B. Harms: I appreciate Mr. Pasnak's interest in the paper. His indication that the experimental results are generally confirmed by tests conducted at the Naval Ordnance Laboratory is encouraging.

No attempt was made during the performance of the tests reported in the paper to separate the core loss into its hysteresis and eddy-current components. The test program was designed to find out what happened to the magnetic properties on a quantitative basis and to view the causes simply on a qualitative basis. Since it becomes easier to magnetize iron as the temperature increases it would appear, as the discusser suggests, that the hysteresis loss would decrease. I have not obtained data to say how much this decrease is or what its content is relative to the eddy-current loss, and I look forward to Mr. Pasnak's report on his work and on the measurement and analytical techniques he used to separate the core loss into its components.

The Simultaneous Transmission of Television and Telephone Multiplex Over a Single Microwave Channel on the Trans-Canada TD-2 System

THIS YEAR, a *TD-2* radio relay system[1] will span Canada from Halifax to Victoria. Certain sections of the network are designed to handle television and telephone circuits simultaneously on the same broad-band channel. It is the purpose of this paper to describe the transmission and terminal-equipment aspects which make this new technique possible and economically attractive.

The idea of stacking or "double-decking," as this technique is termed, was prompted by a demand for a limited number of long-haul telephone circuits coincident with a requirement to provide nationwide television service. To test the feasibility of stacking and to accumulate operating data, a successful field experiment was conducted by the Bell Telephone Laboratories early in 1954 on a 1,133-mile *TD-2* route with the use of standard telephone and television terminal equipment. In this experiment, two conventional high-pass–low-pass filters were used to combine and separate the signals at the *TD-2* terminals. Field results indicated that two or three telephone supergroups,[2] of 60 channels each, could be stacked in the 6- to 7-mc (megacycle) region above the television signal. While the tests and study indicated that NTSC (National Television Systems Committee) color programs could probably be satisfactorily transmitted over a stacked system, the final decision to proceed with the stacked installation was based on the assumption that the system would be unstacked before color programs were transmitted.

Fortunately, a *TD-2* channel and its associated FM (frequency modulation) transmit and receive equipment can be employed without modification. The terminal video circuit arrangements, however, require considerable engineering in order that these two distinctly different types of service may be properly combined and transmitted simultaneously. The video installation arranged for stacking is a specially engineered job at most radio terminals. Variations arise due to: 1. different telephone traffic and television broadcasters requirements, 2. the existence of three types of combining filters, and 3. transmission considerations to maintain high-quality circuit performance that long-haul communication service demands.

Fig. 1 illustrates the geographical position of the Trans-Canada *TD-2* route with the stacked sections shown in heavy lines. On September 30, 1956, television was inaugurated on the Toronto–North Bay–Winnipeg sections. The progressive addition of telephone circuits began in December. One supergroup is provided for Toronto–North Bay telephone service and two supergroups operate between Toronto and Winnipeg. These latter supergroups pass through the North Bay telephone terminal at intermediate carrier frequencies. The *TD-2* channels between Toronto and North Bay are thus loaded with 60 more stacked telephone circuits than elsewhere on the system. The westward route to Calgary and the eastward route between Quebec and Saint John, N.B., both of which are in operation, handle one television signal each way together with a maximum of 120 2-way telephone circuits. As the traffic load approaches its limit on sections of the radio network, the stacked arrangement will be discontinued and each service will be carried on separate radio channels.

The transmission considerations, terminal circuits and tests, associated with the stacked arrangement of television and telephone circuits, will be described in detail, followed by a discussion of a few of the important transmission problems that confronted the engineer when the first stacked route went into service in the autumn of 1956.

Transmission Considerations

FREQUENCY ALLOCATION

The *TD-2* System[1] is designed to transmit a base-band signal extending from virtually zero frequency to approximately 10 mc. In the standard system the signal is either a television signal whose significant energy extends from the bottom of the band to about 4 mc, or a block of 480 to 600 telephone channels arranged in frequency division multiplex and extending from about 64 kc to about 2 to 3 mc.

In the stacked arrangement described in this paper both a television signal and a limited number of telephone circuits are combined for transmission simultaneously over a single broad-band radio channel. The frequency allocation plan is shown in Fig. 2. As before, the television signal extends to slightly over 4 mc. The telephone channels extend from 6,012 to 6,748 kc and provide a maximum of 180 channels. These are derived from channelizing equipment developed for the *L-3* coaxial carrier system.[3]

RADIO CHANNEL NOISE CONSIDERATIONS

The typical noise spectrum of a *TD-2* channel is shown in Fig. 3. This represents the noise per cycle in a *TD-2* channel, arbitrarily plotted in decibels relative to the noise at 5 mc. This noise largely arises in the converter and preamplifier associated with each *TD-2* repeater, the absolute magnitude of the noise depending upon the number of repeaters in the circuit.

It will be noted that over about 500 kc the noise power per cycle increases 6 db (decibels) per octave of frequency. With the same FM deviation per telephone channel, the double-decked channel may therefore be expected to be at least 10 db noisier than the worst channel in the all-telephone case.

However, if pure FM were used, the noise in the worst channel in the all-telephone case would be some 15 db higher than the best channel; see Fig. 3. Using pre-emphasis, the deviation of the top

channel may be increased and the deviation of the bottom channel decreased, thereby obtaining an improvement in noise in the worst channel of approximately 3 to 4 db. Since the inherent noise on the top double-decked telephone channel is only 1 db greater than the noise on the bottom channel, pre-emphasis networks in the wire line entrance link are of negligible value and are therefore not installed. With the same deviation per channel, the total fluctuation noise in the double-decked channels may not be 10 db higher but actually about 13 to 14 db higher than in the all-telephone case. The field test results showed that this noise impairment may be reduced to 7 to 8 db by increasing the normal level of the *L* carrier 6 db and decreasing the normal television level 3 db at the FM transmitter input. Adverse intermodulation effects, as the result of these level changes, were not evident during the test.

Intermodulation Considerations

The frequency-modulated carrier may be distorted in amplitude and phase to a small degree by any amplitude and phase distortion in the IF (intermediate frequency) and RF (radio frequency) portions of the system and this gives rise to intermodulation products in the detected base band and signal. These products may originate within the television signal or the telephone channels, or from the combination of both signals. Intermodulation products produced by the television signal alone may degrade the picture itself and may also introduce spurious energy at the second harmonic of the color carrier. Products involving the telephone channels alone may fall in the band occupied by the television signal or may fall back into the telephone channels themselves. Other products involve both the television signal and telephone channels simultaneously.

A monochrome television signal produced by scanning is composed of concentrations of energy located in frequency regions harmonically related to the line and field-scanning frequencies. Experience has indicated that with the normal degree of phase and amplitude equalization achieved in the *TD-2* system, the intermodulation distortion is unimportant.

The NTSC color signal has, in addition to the frequency components just mentioned, a strong component of energy at approximately 3.58 mc with concentrations on either side of it. This energy is spaced at intervals of the line-scanning frequency of approximately 15.75 kc; see Fig. 2. Amplitude and phase distortion of the FM wave give rise to a distortion spectrum of this energy centered at 7.2 mc, with rapid fall-off on either side. The magnitude of this distortion spectrum depends largely on the residual linear envelope delay distortion in the RF and IF portions of the system remaining after normal phase equalization.

Sufficient frequency space between the top of the television signal and the bottom of the band allotted to the telephone channels must be allowed in order to combine and separate them without excessive phase distortion in the television signal. Furthermore, the top end of the telephone band must be somewhat under 7.2 mc so that the energy in the distortion spectrum of the NTSC color signal, if transmitted, will not interfere significantly with the telephone channels. For these reasons, the telephone channels have been restricted to a frequency bandwidth of 736 kc lying between 6,012 and 6,748 kc.

Second-Order Distortion Products

Amplitude and phase distortion of the FM wave may produce all orders of distortion of which the second order has been found to be the most significant in the present application. In particular,

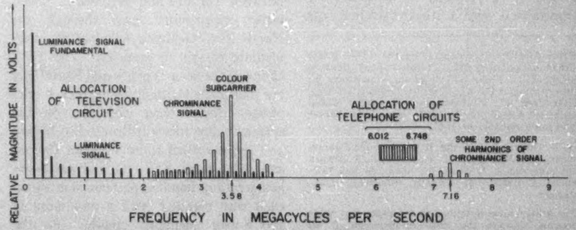

Fig. 2. Frequency composition of NTSC color television signal with telephone circuits arranged for stacking on the same TD-2 channel. One out of every ten frequency components is shown

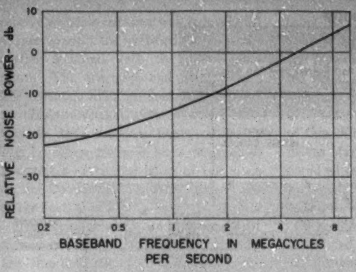

Fig. 3 (left). Relative noise power per cycle at FM receiver

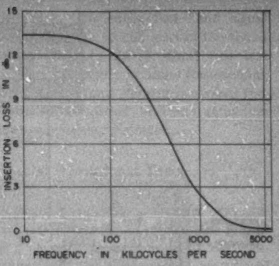
Fig. 4 (right). Loss frequency characteristic of television pre-emphasis network



second-order difference products involving the telephone channels themselves, will fall into the 4.2-mc bandwidth occupied by the television signal. Since the telephone channels are spaced at 4-kc intervals, this interference spectrum will begin at a base-band frequency of 4 kc, where the number of possible difference products is a maximum, and will extend to a frequency of 736 kc equal to the band covered by the telephone channels. These products may appear as interference in the received television picture. This interference can be reduced by dropping the level of the telephone channels or by raising the level of the television signal at the FM transmitter. Lowering the telephone level is more effective.

In addition to the intermodulation products just discussed, there will also be products involving both the television signal and the telephone channels simultaneously. The most critical of these is a second-order sum and difference product involving the strong component of the television signal at approximately 15.75 kc and any particular telephone channel frequency. Since the telephone channels are spaced at 4-kc intervals, these products will appear in the telephone channel located 15.75 kc away from the channel originating the product, and will appear as intelligible although distorted crosstalk. Similarly, other products involving harmonics of the line scan frequency of 15.75 kc will be generated.

OPERATING LEVELS AT FM TRANSMITTER

The relative operating levels of the combined television and telephone channel signals at the FM transmitter input are based on a compromise of the interacting effects discussed in the foregoing. Thus, if the telephone channel level is dropped, interference into the television signal is reduced. However, while the intelligible telephone crosstalk remains unchanged, the amount of fluctuation noise in the telephone channels increases. If, instead, the television signal level is lowered, interference into the telephone channels is reduced, but distortion from the telephone channels into the television channels, as well as fluctuation noise, is increased.

The inherently lower noise at the low end of the video band achieved by the use of FM has permitted the use of a substantial amount of pre-emphasis of the television signal, as shown in Fig. 4. This reduces the relative deviation of the low-frequency components of the television signal by about 14 db and affords a corresponding reduction in the intelligible crosstalk in the telephone channel without appreciable penalty to the television signal.

The optimum relative operating levels of the two signals represents a balance between these various factors. Satisfactory intermodulation performance, however, imposes tolerances on the amplitude and phase distortion in the IF and RF band which are substantially more restrictive than when the signal is all-telephone or television only.

COMBINING FILTERS

The art of juxtaposing isolated blocks of information in a given frequency band developed contemporaneously with the conception of carrier telephony, but a new technique is involved in transmission via radio of an NTSC television signal simultaneously with a limited but relatively large number of long-haul circuits.

A combining filter, designed specifically for the purpose of combining and separating the two bands at transmitting and receiving terminals, accomplishes this operation by means of its low- and high-pass filter sections. The low-pass television circuit of the combining filter must be equalized for constant loss and constant phase delay at all frequencies up to 4.5 mc. Also, high-frequency ringing in the television path should be minimized. This requires the delay equalization to extend well into the cutoff region of the low-pass filter; see Fig. 5.

In the initial stages of the development, a preliminary combining filter was designed. Subsequent testing indicated that not more than eight of these filters could be used in tandem. An improved filter design was therefore developed which gave less distortion in the through circuit. This new branching filter performed the same function as the original filter. A combination of these two filters in tandem is required in all video receiving circuits at terminal points to suppress undesirable high-frequency delay distortion; see the receive circuit arrangement in Fig. 6.

The components and the method of assembling the filters are the same as those used in filters for the *L3* system television terminals.[8] The filters provide a communication system which gives television transmission through a number of stacked sections in tandem comparable in quality with that of a standard *TD-2* system.

Terminal Equipment

A fundamental requirement in the design of telephone and television transmission systems is that any modification

or new development must be capable of operating with previously installed systems. This means that provision must be made to interconnect new systems into the pattern of the existing plan. The establishment of a *TD-2* radio relay system requires interconnections with telephone terminal equipment and a television operating center[4] (TOC) at terminal stations. This is accomplished with "wire line entrance links" and "video interconnecting circuits" respectively.

Standard wire line entrance links[5] and video interconnecting circuits are installed at a number of *TD-2* terminals across Canada. They appear at those terminals on the network that originate and terminate television and telephone circuits on separate radio relay channels. There are eight major terminals and an equal number of bridged locations where the video circuits are arranged to transmit television and telephone signals simultaneously on the same radio circuit. Simplified wire line entrance links and modified television interconnecting *TD*-TOC circuits were developed and equipped with combining or branching filters at these latter locations. With the exception of these filters, the video interconnecting circuits require no basic developmental work but considerable rearrangement including additional standard components.

Video Interconnecting Circuits

One or more of three types of video interconnecting circuits are installed at all *TD-2* radio terminals. The TOC-to-*TD-2* radio interconnecting circuit transmits television signals from a television operating center to an FM transmitter in the nearby *TD-2* radio room. The *TD-2*-to-TOC video circuit accepts the television from the FM receiver and transmits the signal to the local TOC. The video bypass circuit, which is a new development, essentially interconnects an FM receiver with one or two FM transmitters in the same *TD-2* radio room. It also provides interconnections with both foregoing interconnecting circuits.

Video bypass circuits are installed at *TD-2* terminals, arranged for stacked television and telephone circuits on the backbone radio route. The geographical locations are Saint John, Quebec, Toronto, North Bay, Winnipeg, Regina, and Calgary. The bypass circuit avoids the necessity of routing via the TOC those incoming television signals destined for distant points. Repeated de-emphasis and pre-emphasis, Fig. 4, of the television signal is avoided and at a number of terminals this circuit permits the replacement of the combining filter with branching filters in the through circuit. The number of combining filters in tandem is therefore held to a minimum along the microwave route. The quality and reliability of picture transmission are hence retained with the bypass circuit.

A typical video bypass circuit is illustrated in Fig. 6. The equipment arrangement at some locations is more complex than at others and may include three or four different circuit variations. In contract, other *TD-2* terminals, mostly those points bridged off the main route, are equipped with simple received and transmit interconnecting circuits. When the various sections are unstacked, the interconnecting circuits will be restored with the bypass circuit and dropping filter removed.

Wire Line Entrance Links

In contrast to the numerous video interconnecting circuits for stacked *TD-2* channels, only one type of transmit and receive wire line entrance link is developed to interconnect the modified *L3* telephone carrier terminal with the *TD-2* radio room. The transmit and receive wire line entrance links are installed at *TD-2* terminals on stacked sections of the Trans-Canada route shown in heavy outline in Fig. 1. These entrance links, designed to transmit a restricted band of telephone carrier frequencies, are illustrated in the upper portion of Fig. 6.

The relatively large number of *L* terminals and TOC's along the route, and the impracticability of combining and separating these two services at IF, have produced a variety of terminal interconnecting circuits in an effort to maintain the over-all transmission objectives. While some additional units have been required as a result of this variety they will all find ready use in expanding TOC's when the stacked arrangements have served their purpose.

Initial Transmission Tests

All microwave channels of a *TD-2* system are normally subjected to a number of transmission tests prior to service. These include for example, measurements of video response, base-band noise, 2-tone distortion, and differential phase and gain. Tests and adjustments are also made on the FM transmitting and receiving terminals to ensure that they do not produce any undue transmission degradation of the signal.

Phase correction is normally provided at the 70-mc IF frequency in order to achieve adequate intermodulation performance when the system is used for telephone transmission. However, the application of stacking to a *TD-2* radio channel imposes stricter requirements on phase distortion on the system, if the performance of the video and telephone circuits is to be satisfactory. Thus certain special preservice tests were made on the stacked system. First, the over-all phase characteristic of the system was examined most critically in order to identify and eliminate, as far as feasible and necessary, the various sources of envelope delay distortion; second, the optimum input levels to the FM transmitter were determined experimentally for best performance of both the television and telephone channels. These tests are discussed more fully in the following.

ENVELOPE DELAY DISTORTION

As the first step in minimizing the envelope delay distortion, a visual inspection was made of the curve of envelope delay distortion in the microwave system, using the visual delay set, which is standard test equipment for the *TD-2* system, and is arranged to swing the RF carrier ±7 mc at a rate of 100 cycles per second, and to superimpose upon the signal a 277.78-kc "flutter" signal. The phase of this flutter signal as the FM carrier moves throughout the IF band, is compared with its average phase. This comparison is displayed upon an oscilloscope at the receiving end.

When the visual delay set was used on the looped Toronto–North Bay–Toronto circuit, it was evident that the circuit required envelope delay distortion slope equalization. Further, while envelope delay distortion ripple was observed on all channels, it was found to be especially severe on one particular channel. Specifically, this distortion consisted of ten ripples across the IF band with a peak-to-peak amplitude of approximately 100 millimicroseconds. Calculations showed that this was well in excess of the design objective, and it was concluded that some fault in the form of an impedance mismatch existed on the system. By looping back the signal from the visual delay set at each auxiliary repeater station and noting the change in distortion ripple, a fault was located at the fifth repeater station west of Toronto. This proved to be a mismatch at the antenna caused by an improper connection of the flexible wave guide.

The visual delay set permitted phase equalization of a looped circuit on a visual basis and thus increased the accuracy with which phase equalizers could be placed in each channel.

TWO-TONE TEST

It was apparent that the major source of intermodulation in the telephone channels was second-order distortion involving any particular telephone channel and the strong component of energy in the television signal at 15.75 kc. Therefore a 2-tone test was used to evaluate, on an out-of-service basis, the amount of speech intermodulation to be expected for various amounts of delay distortion. This test consisted of simulating the *L* carrier and television frequencies by applying a 6.5-mc sine wave and a 15.75-kc sine wave into their respective inputs of the filter. By noting their sum or difference products on a narrow-band transmission measuring set at the receiving end of the *TD-2* system, it was possible to observe and evaluate the changes in the product level as phase equalizers were inserted in the system.

While, strictly speaking, in FM the amplitude of any modulation product may depend on the entire base-band signal rather than the specific part of the signal which produces the product, this test appears sufficiently accurate for assessing the potential improvement in system performance associated with any reduction in envelope delay distortion.

Special Operational Tests

Regular television service was inaugurated between Toronto and Winnipeg about 2 months prior to the commencement of the special operational tests. These tests were carried out to determine final optimum operating levels, to measure intermodulation between the television and carrier, and to measure noise conditions.

Initial test loading of the system was arranged during non-TV periods by using an Indian-head monoscope pattern as the television component and by bridging three supergroups (180 voice channels) off the Toronto-Montreal *TD-2* system for use as the *L3* carrier component. A continuous recording of this latter loading was kept in order to determine the periods of heaviest telephone usage. It was thus possible to test the system under peak-load conditions, which could be verified by reference to the recording.

The first circuit, arranged for testing under the afore-mentioned conditions, consisted of a Toronto–North Bay–Toronto loop, covering a total distance of approximately 400 miles. By using a looped circuit, it was possible to compare the quality of the outgoing and incoming television picture and to obtain noise readings on the individual voice channels of the *L3* carrier system. During these tests, observations were also made at North Bay.

As was anticipated, the relative deviations for the television and telephone channels for optimum deviation had to be determined experimentally under actual operating conditions. When the television signal produced too high a deviation, the cross-modulation in the telephone channels was unacceptable. When it was too low, the television signal was unacceptable. An optimum balance between the two was reached and then, by an intensive program of reducing the envelope delay distortion, as mentioned previously, the desired performance standards for both television and telephone channels were achieved.

The Toronto-Winnipeg system is approaching its stacked capacity and engineering is well under way for the provision of a third radio channel. This was necessary because present traffic requirements for Trans-Canada telephone circuits have exceeded the original forecast.

Experience gained to date shows that stacking of television and telephone circuits is entirely feasible and is economically attractive where the telephone circuit requirements are limited and system lengths range from about 200 to 1,000 miles. The application of stacking has proved a worth-while contribution economically, and the transmission objectives which were defined as acceptable in the initial planning stages have been met.

Error-Checking for 5-Channel Telegraphic Tape

R. A. BARBEAU
MEMBER AIEE

THE USES and the advantages of 5-channel paper tape are well recognized in the business world. Paper tape has been used for many years for message sending. Its use in telegraphic communication equipment serves as the life line of communications for many businesses. In recent years the decentralization of factory equipment and the general growth of businesses have made the transmission of accounting or scientific data between cities increasingly important. The rapidly expanding use of commercial computers and business machines will result in a further increase in the volume of data that must be communicated between cities. As more and more data are communicated, one becomes aware that a major improvement is required to refine the system, especially with regard to error handling. There is a practical limit on the improvements that may be made in transmission facilities to decrease the error rate. However, these improvements, plus a system of error detecting, could provide a highly efficient system that would be able to handle large volumes of data with a minimum amount of error-handling techniques.

This paper will describe an error detection system that is compatible with present-day telegraphic communication facilities, including automatic switching centers. It will describe a complete, practical system that has been tested and has proved to be highly efficient. The paper will discuss in detail the systems problems and engineering problems, and how they were approached.

Systems Problems

Systems used in the past have made use of group total control for the detection of errors. Information prepared at a point of origin, such as invoice writing, may be contained in a roll of tape 100 to 200 feet in length. At the point of origin a group total is compiled for the important items that should be checked, such as quantity of items or amounts of money. As shown in Fig. 1, this information is transmitted to a distant reception point, the conversion to other means of storage takes place, and it is followed by an attempt to balance to the control figures. Should the control totals fail to balance, there is at present no easy means of indicating or pinpointing where the error might have occurred in this group of records. It can, in fact, necessitate the reprocessing of a new tape at the point of origin for the full amount of information that did not balance. This is not only time-consuming and costly, but inefficient, because both correct and erroneous information is reprocessed.

It is known that there are five areas in which errors may occur, as follows:

1. The preparation of paper tape, especially when done by a manual method.
2. Reading of the paper tape for transmission.
3. Actual transmission of data over leased lines or other media.
4. Reperforation of paper tape at a distant point of reception.
5. Reading of tape for conversion.

To have a practical system of error detection, any rearrangement of codes must not have an adverse effect on communication equipment now in use, such as page printers or other subscriber sets. In fact, equipment already available in the field must be utilized. Rearrangement of codes to include checking must not make unintelligible or otherwise affect information printed on page printers. Basic telegraphic code arrangement rules must not be violated.

Any checking code must not interfere with switching centers now in existence. As an example, a figures-shift *H* character must not be used for record checking because this code has its primary use as a switching center control.

The present economy in transmission time must be maintained, which means that any added characters for checking must be kept to a minimum.

In a complete system that is to receive broad usage, any proposed device capable of producing checkable tape must accept electrical inputs from other business machines.

The problem of operator error with a manually keyed machine is probably one of the most difficult items to handle in the over-all system of error control. Many operator errors may be eliminated by a simplified error correction procedure and by a reduction in the number of operational decisions required of the tape punch operator.

Design Goals

After the systems problems mentioned had been reviewed, it was realized that design efforts should be concentrated in the areas of tape preparation and tape

---

Paper 58-2, recommended by the AIEE Data Communication Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted July 12, 1957; made available for printing October 8, 1957.

conversion. It also became evident that, to detect error at the converter, some type of "piggy-back" check should accompany the information in the form of a tape code.

The major goal was to design and supply an entire workable check system from start to finish, from the preparation of tape to the finished accounting medium, such as cards, for example.

Another important design goal was aimed at the operator preparing the punched tape. It was recognized that the operator plays a very important part in the accuracy of the over-all system. Consequently, any changes that would simplify the operator's work in the proper manipulation of keys, the reduction of key strokes, or other improved operating procedures would aid in producing a more accurate and better tape from an over-all systems standpoint.

Another objective was to design an error deletion routine that would be fast, automatic, and reliable, possibly controlled by a single keystroke. This would serve to relieve the operator of multiple decisions during the tape preparation.

The design of the system should keep total costs in line with the results gained. The system must contain the desired accuracy without imposing a hardship on the required transmission time, and it must not require changes in present telegraphic transmitting facilities.

The code arrangement, if changed to include checking, should not affect any of the existing systems in telegraphic communications. Particularly, it should not affect functions attributed to automatic switching centers. Also, such a code arrangement must be adopted that can make use of all telegraphic facilities.

Preparation of Checkable Tape

A variable length block of information was decided upon as a unit record of information. A unit record of this nature would fit a telegraph page printer, a typewriter, or a tabulating card. It was found that a unit record which corresponded to a line on a printed page was compatible for both error deletion and error detection.

ERROR DELETION

If deletion is to be automatic, an identification means must be used to signify the beginning of a record and again to indicate the point of error. The machine preparing the tape is basically a punching mechanism that does not contain a multiple-channel tape-reading station. It was decided to use a notch on the top edge of the tape for identification, which would allow for ease of sensing and would not require interpretation by a multiple-channel reading station. A notch is located between the last character of the preceding unit record and the first character of the new unit record. Another notch is used to identify the point of error.

If the operator recognizes a mistake during a given unit record, the depression of an error key notches the tape at the point of error. Automatic backing up of the tape to the point where the record started, as shown in Fig. 2, and automatic deletion or superimposing by the delete code will take place until a notch is read indicating the point of error. The notch in the tape will not affect the communication tape readers because its location is outside the operating area of the reading and run-out pins.

This manner of automatic error deletion fits a requirement of manual operation. No decisions are needed on the part of the operator other than to depress the error key at the time the error is recognized and to retype the line. The notch in the tape signifying a unit record is entered automatically at the beginning of every line. It is possible for the operator to make a correction for that line no matter where in the line she recognizes the error. The depression of the carriage return key may be likened to a motor bar depression at the end of an entry. The entry may be corrected at any time prior to the depression of the motor bar operation. This single decision by the operator has proved very effective and accurate in the preparation of paper tape.

CHECKING CODE

A decision was made to arrive at a piggy-back code by counting the code bits in the record. This code was then attached as part of the record to be transmitted. The decision to count the bits in a record blended with the fact that it could be directly coded to the figures-shift digits 1 through 9 and zero. It was decided that the check digit count would be the units position of the total count of the number of holes appearing in the tape following a beginning of unit record identification and including all of the end of record identification codes. It was not felt that a 2-column check code was required, and further tests have borne out the fact that the single-column check code is sufficient.

The generation of a check code by unit record signifies that a beginning of record identification must be used, as well as an end of record identification, because the same method of checking the information at the point of conversion must take place in the system. The identification of the unit record for the operation of a checking code cannot be the notch because the notch will never appear on the reperforated tape.

is used for error deletion and as a run-in code, the figures (FIGS) shift code was selected to identify the beginning of unit record. The carriage return (CR) and line feed (LF) codes required for page printers were further expanded to provide an end of unit record identification. The check code requires a FIGS shift code, and the CR function requires a second nonprinting code. The identification of the end of unit record is then comprised of a 3-unit code group, namely, CR, FIGS, LF. The check code follows the end of unit record identification and becomes part of the unit record. A complete unit record of tape is shown in Fig. 3.

The FIGS entered between CR and LF becomes a very distinctive identification mark for the new checkable tape, as contrasted with a noncheckable tape containing CR, LF, in that sequence.

During the perforation of paper tape at the point of origin, the entry of the FIGS shift code at the beginning of a unit record conditions the machine to clear the adding counters, makes a reset zero check, and instructs the machine to add all information following this beginning of unit record identification. When the case of the next code is alphabetic, LTRS shift follows the first FIGS shift. While intelligence is being entered into the unit record of tape, addition of the holes making up the 5-channel code is in process throughout, including the end of unit record identification. The total units count of the number of holes will be recorded in a telegraphic code after the LF.

Automatic Cycles

Tape punch circuitry was designed to accept a single pulse in order to enter automatically CR, FIGS, LF, check code, and notch FIGS denoting the end and beginning of unit records. This single pulse is generated upon the depression of the typewriter carriage return key. The depression of the TAB key on the typewriter enters G, FIGS or FIGS, G, LTRS automatically into the tape. A 3-row keyboard arrangement was adopted, and the operation of the basket shift mechanism automatically enters the proper shift codes. These automatic cycles contribute to tape accuracy and ease the operator burden.

In certain cases involving page printers, it is desirable to separate the printed check code from the body of the printed record. This is accomplished by having the typewriter carriage return key depression automatically insert CR, FIGS, LF, check code, G, and notch FIGS in the tape. The G code operates the tabulating mechanism in the page printer. It is also desirable in some cases to insert LF codes following the beginning of record FIGS code. Subsequent depressions of the carriage return key insert the LF code only.

Redundancy Checking

Whenever two pieces of equipment are electrically connected, some sort of feedback is desirable to ensure the accuracy of both devices. It was decided that the code-generating device should furnish a redundancy 6-channel code, five of which were the telegraphic channels; see Fig. 4. Five telegraphic channels would be punched in the paper tape, and the sixth would operate a dummy punch. All six punches would operate circuitry to effect an odd check.

Circuits in the code-generating device are so designed that the failure of a single relay point or a single diode will cause no more than the omission of a single bit, or all bits, either of which omissions may be detected by the odd count redundancy type of check. This check takes place during the punching of every code in the tape.

Reliability Checks

In keeping with the accuracy of the system, reliability checks were added to ensure the earliest possible detection of machine malfunction and thus avoid lost time throughout the system.

As a supplement to redundancy checking, or when a code-generating device is not capable of supplying a sixth channel output, the design of the mechanism and circuitry provides a further accuracy check of the output medium and punching mechanism. On every tape-punching cycle a check is made between the input and the actual punching for each channel of tape information. Electric pulses, conditioning channels 1, 4, and 5, for example, are compared with actual holes perforated in channels 1, 4, and 5. The conversion of the decimal check digit in the counter to a telegraphic tape code is done on a 6-channel basis in keeping with redundancy checking.

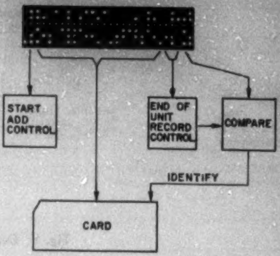

Fig. 5. Tape-to-card conversion

To assure the accuracy of the accumulated check digit, two sets of counters are used. These counters are fed by relays whose accuracy has been checked by previously mentioned methods. A comparison is made between these counters on each tape-punching cycle.

A second notch-reading pin is employed to check the accuracy of the first notch-reading pin. It provides assurance that a good record will not be overrun during error deletion. Both notch-reading pins are used to check tape movement at the beginning of every record.

When malfunctions are detected by these means, a signal locks the typewriter keyboard to prevent further processing of tape. The operator may then depress the error key, deleting the unit record, and attempt to retype the line. Thus unit failures are caught, and the operator is prevented from preparing faulty tape.

Paper Tape Transmission

The tape prepared as described may now be transmitted over commercial communication equipment, and reperforated tape prepared at the point of reception. It should be noted that this system does not require changes in standard equipment, and any improvements made in service will tend only to improve the system.

Error Detection During Conversion

Since the reperforated tape is checkable by unit record, its conversion to an accounting medium with error identification by unit record may be accomplished. Although a discussion of the systems aspects of a tape-to-card converter would supply a background for the following discussion, it is felt that the conventional converter functions might be indistinguishable from the detection means incorporated in the machine. Therefore this section of the paper will deal primarily with the error detection phase of conversion.

As previously listed in the systems problems section, errors can occur during the reading of tape for transmission, during transmission, during reperforation, and during the reading of tape for conversion. In the design of a tape-converting system, a careful review must be made of the types of errors that will be encountered, and enough intelligence must be built into the machine to insure fail-safe operation. This intelligence must also include reliability checks.

The error-detecting device attached to a tape-to-card converter contains primarily a single-position decimal counter under reset and add control of the first FIGS in a record. Accumulation of the code bits takes place in much the same way as in the device which prepared the checkable tape. The piggy-back check code in the tape is compared with the total in the counter under the control of the end of unit record codes, CR, FIGS, and LF. During tape reading, the analysis of the first FIGS code of a record resets the counter, makes a zero check, and conditions the counter to add succeeding code bits. The body of the record is punched into the card simultaneously with tape reading.

When the tape converter analyzes the end-of-unit record codes, CR, FIGS, LF, the machine is instructed that the next character to be read in the tape is the check code. During the reading cycle following the LF code, a comparison is made between the accumulated decimal count in the converter and the check code appearing in the tape. When the two numbers are in agreement, the converter gives a check signal for proper card identification. During the comparing cycle, if the digit appearing in the counter is in disagreement with the code which is read in the tape, the converter gives a noncheck signal for proper error identification of the card. Because the check code appearing at the end of a unit record is strictly for accuracy checking, it is not available for conversion purposes. When the figure shift G code has been inserted between unit records, the G is not made available for conversion purposes.

UNIT RECORD CONTROL

For efficient use of this type of check digit appearing at the end of a unit record, it is necessary to have close control over defining the record limits, both the beginning and the end of unit record.

The primary use of the beginning of record FIGS code is to control subsequent adding of the code bits of the unit record during conversion. To effect a control of a record that has a mutilated beginning of unit record FIGS code, the conversion of tape codes conditions an error memory device. The device supersedes check code comparison in order to effect error identification of this record.

Previous error-detecting experience led to setting up controls using all three end-of-unit record identification codes in a given sequence. When all three end-of-unit record codes are present, CR, FIGS, LF, in that order, the comparing cycle output depends upon agreement between the counters and the check code in the tape; see Fig. 5. If one of the three end-of-unit record codes has been mutilated, the error memory device is controlled and will cause the noncheck signal during the comparing cycle. Examples of these code mutilations follow:

Space, FIGS, LF
CR, V, LF
CR, FIGS, CR

The converter will acknowledge any two of the three end-of-unit record codes in correct sequence and cause comparing on the correct cycle. This comparing cycle control is not effective when an LF code follows the beginning of record FIGS.

If CR, LF appear to the converter in this order, they cause automatic comparing on the next cycle with an automatic noncheck signal output. This comparison serves two purposes:

1. Indication that noncheckable tape is being processed.
2. Prevention of switching directive codes from being processed as a correct record.

When the CR code is sensed not in its proper position, the error memory device will be operative; for example, if a channel 3 space code has been shifted to a channel 4 CR code in the body of the unit record.

Prior to testing this error detecting system, it was recognized that certain types of compensating errors (such as the dropping of one bit on one code and the adding of another bit on another code within a unit record) would not be detected solely by the check code appearing at the end of the unit record. It was also realized that certain types of transmission failures might result in the dropping or adding of ten bits of information. During the testing of this system, it was found that the compensating errors within a unit record were very infrequent, and the occurrence of an error of ten was extremely rare. The logic of the converter, prior to the application of error detection, could already take care of some of these compensating errors or errors of ten, and these checks were available at no extra expense to the system.

Conclusions

Numerous papers have been given on the subject of error detection, mentioning a check code. However, it is felt that for a system to be practical it should contain close limit control on the checking block. These controls make it possible to use a variable length record with a high efficiency of error detection. The system described here is aimed primarily at compatibility with the existing commercial communication facilities.

Conventional error handling in accounting systems is time-consuming and costly, because error detection is normally done by control groups at a point in accounting later than tape conversion. The checking system described in this paper allows for error detection by unit record during the conversion process. Reprocessing or retransmission of only the erroneous information saves considerable time. This system proves to be an accurate, practical checking means for paper tape.

Digital and Pictorial Photographic Electronic Recorder

R. G. McPHERSON
ASSOCIATE MEMBER AIEE

I. A. SONDERBY
NONMEMBER AIEE

A FILM DATA-RECORDING system is described which combines the advantages of pictorial and digital recording. This combination of photographic and digital techniques provides a record containing a picture of the event of interest with the adjacent frame used to record a digital code, which may be used to provide a record of instrumentation, time, or other identifying information.

The advantages of film recording include high density recording (systems of 6,000 bits per square inch are in operation with work reported on systems approaching 10^6 bits per square inch); high readout rates (systems of 200-kc bit rate are in operation and experimental 2-megacycle systems have been in operation); and high data storage per cubic foot, as demonstrated by microfilm files now being used. Automatic search through film reels based on recorded data is possible.

Data Recording

The upper limit of data-recording density on the film is determined by considering film tolerances; registration accuracy in recording and reading; effects of dirt, dust, and scratches; and complexity of readout and recording equipment. Experience with film reading projects indicates that data spots 10 mils by 10 mils are a practical size for the digital data. For 16-millimeter film this corresponds to rows of data of approximately 40 bits or 4,000 bits per inch of 16-millimeter film. With dimensions of 10 mils by 10 mils, successful data recorders and readers have been designed and operated. While it is certainly possible to provide a much greater density of data per square inch of film, the considerations of film dimensional stability with temperature, humidity, and age for systems intended for commercial type use indicate that these dimensions are practical limitations. In addition, for data rows in excess of 40 bits, the problems of providing a clock become somewhat more difficult.

Miniature incandescent lamps (0.069-inch diameter) have been used for the recording head light source. They are available from a number of companies and are a standard item in use for medical applications. Lamps of this type have been tested with over 4.6 million cycles of on-off operation without failure and continuous operation of over 800 hours without failure. The power requirement is 90 milliwatts at one volt. Requirements for this recorder system include analog-to-digital conversion with the digital output capable of providing one volt at 90 milliamperes. Examples of encoders that may be used include the commutating code wheel shaft position-to-digital code converter, of which a number of types exist. Relay devices may be used, as may transistor switches driven from a flip-flop register.

At The Magnavox Research Laboratories, several film data programs are in process or have been completed. One system recently completed provided for the recording of airborne instrumentation data consisting of up to 90 bits of data at rates up to 2,880 bits per second. In addition, pictorial data are collected to show the pilot's observations during the tests in question. The airborne equipment consisted of analog-to-digital conversion equipment, a timing information generator, and the controls necessary to start and stop recording based on events detected in the aircraft. The recording rates required were 16 and 32 frames per second.

Development work on design of a recording head included study of electroluminescent-cell light sources, small cathode-ray tubes, and miniature incandescent lamps. After consideration of the limitations of each of these recording methods and some experimental work, it was determined that the incandescent lamps recorder was the better choice for this application. Fig. 1 shows the recording head assembly used for this airborne application. The recording head contains 90 lamps and is approximately 1/2 cubic inch in volume. Fig. 2 shows the type of record obtained. For 16-millimeter film, one and one-half frames are used for picture area, one half a frame is used for data. The picture and digital data are recorded simultaneously through the shutter.

In the airborne recorder application three voltage signals, whose amplitudes were proportional to the quantity to be measured, were used to provide drive signals for three servo units. The commutating type of code wheels were used for the shaft position to digital conversion. This system provided a digital record on the film of ±15 degrees measured in 1-mil increments. In addition, measurements or indications were provided for the type of armament, time, slip or skid, prerun condition, and armament action. The airborne recorder is shown in Fig. 3.

Data Reader

Several methods of reading or extracting the information from the film were investigated. These methods are classified in three groups: optical-mechanical, cathode-ray tube, and storage tube. Each of these has definite advantages, depending on the application in question. Reading rates, tolerances, and reliability are important, and greatly affect the method to be considered.

Of the three types mentioned, the optical-mechanical method is perhaps the simplest in regard to method of readout. An experimental system was constructed using a rotating drum on which were mounted 15 mirrors, each consecutive mirror mounted at a slightly different angle from the previous one. The information to be read consisted of 15 rows of information with six bits in each row. The information itself was represented as 10-mil squares, separated by 10 mils. The field of information, 0.290 by 0.110 inch, was optically magnified ten times and projected on the face of the rotating mirrors. Each mirror in sequence would move its predetermined row of information across the face of a photomultiplier tube and appear at the output as a signal. The upper limits of read rates are determined by the speed of the rotating drum, the amount of information, the precision mounting of mirrors, the frequency limit of the sensing device, and mechanical tolerances.

For data-reading systems of greater density or for those systems requiring greater readout rates, the electronic type of readers have advantages over optical-mechanical systems. An example of this is the flying-spot scanner, a cathode-ray tube for providing a scanning raster

---

Paper 58-29, recommended by the AIEE Recording and Controlling Instruments Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted June 13, 1957; made available for printing November 1, 1957.

R. G. McPherson and I. A. Sonderby are with The Magnavox Research Laboratories, Los Angeles, Calif.

Fig. 1. Recording head assembly

with a multiplier phototube used to convert light changes to electric signal changes. The scanning raster may be made larger than the data field to be covered to allow for registration inaccuracies.

Storage tubes, such as the image-orthicon, the iconoscope, and the vidicon were studied for the film reader function. The iconoscope was made nearly obsolete with the development of the image-orthicon tube. This tube has a much higher sensitivity and efficiency rating compared to that of the iconoscope. In addition, the image-orthicon seemed unfeasible from the standpoint of price and because of its vulnerability to damage. The studies indicated that the vidicon storage tube would be the most practical of the three. Its cost is about $150, whereas the iconoscope ranged from $400 to $600 and the image orthicon was about $1,400. The vidicon is less susceptible to damage from scan failure or from overillumination; it is more compact and allows for more miniaturization in design.

A system using the vidicon as the film reading device is under development and preliminary tests are in progress at The Magnavox Research Laboratories. Tests indicate that a 40- by 60-bit array with each bit 10 mils square, is well within the limits of the reading device. The information matrix is projected on the photoconductive layer on the face of the vidicon. The photoconductive layer is then scanned from within, and signals corresponding to the light areas in the information array are presented at the output. These signals are amplified and are available for use in the decoding or sensing equipment. The vidicon is capable of a 600-line resolution. In this application a 290-line raster is used, which is within normal operation specifications. Effective spot size is approximately 2 mils, linearities in horizontal and vertical sweeps are 2%. Linearities of 1% may be obtained with a high-quality, specially designed yoke. The 40- by 60-bit array is scanned in 16 milliseconds. An overlap of 10% in both horizontal and vertical directions is used to relax tolerances caused by misalignment of the film. The useful area on the face of the vidicon is a rectangle 0.5 by 0.375 inch, requiring an optical reduction from film to vidicon. The resultant four scans per data row assure a preferred scan more nearly in the center portion of a row.

The reading rate for the system described is 150,000 bits per second. Higher rates could be achieved by reducing the size of the coded bits and increasing the number of bits in the array. The reader developed for the airborne recorder system automatically reads the film, frame by frame, and provides a printed record and punched-paper tape output. Readout was accomplished by using an electromagnetic short-persistance cathode-ray tube with a 100-line raster displayed on its face. The light from the flying spot which traces out this raster is focused on the film data area by an object lens which reduced the raster size by a factor of 10. The image of the raster exposed on the film was such that an overlap of the data area was provided in both the horizontal and vertical directions. This overlap takes care of registration inaccuracies which may be associated with the film transport mechanism. The light passing the data field in the scanning process is collected by a collector lens, and projected on the photocathode surface of a multiplier phototube. Thus, light of varying intensity is translated into a signal voltage of corresponding amplitude. The signal voltage so developed is amplified and fed into the system for decoding and printout. The reader is shown in Fig. 4.

Scanning Patterns

For systems with short data rows a free-running clock of the pulsed oscillator or multivibrator type is adequate. By "clock" is meant the provisions of a gating waveform as interrogation pulse to sample the signals from the film data pickup device. This is necessary to identify adjacent bits on the film. Longer data rows (those of 10 bits or more) require either very tight tolerances on film dimensions and readout systems or a clock that is, in some way, synchronized with the film scanner.

Several methods of tieing in the clock with the film data are possible. A beam-splitting optical system may be used in which a fixed clock target is swept by the light source which simultaneously sweeps the data card. In this way the clock and data card signals are independent of time variations of sweeping circuitry. There is a space tolerance, however, that requires rather tight tolerances of the data film with respect to the fixed clock target. For the 10- by 10-mil case this registrator tolerance will approach one mil when the effects of film data dimensional change and recording location tolerances are included in the over-all problem. This method may be used only in systems which include a sweeping light source such as the cathode-ray tube reader. A self-clocking method using multivibrator circuits for the clock has been designed in which the film information changes are used to modify the clock rate or to shift the clock in a direction to resynchronize the clock. In this system, film information is compared with the clock pulse. If the clock is late, it is shifted to occur earlier. This method requires a digital code which ensures the occurrence of film data changes every few bits.

Several methods of scanning the film information have been studied; see Fig. 5. Of the various methods studied, the three which appeared feasible were those involving a full scan with a conventional raster such as used in the system designed and presently in use; a combination of partial scan and full scan; and a combination of vertical and horizontal scan. The full-scan method has been described. For the partial scan, two horizontal sweep rates would be employed, and the shorter sweep would continue until the timing mark was reached. The signal from the interception of the timing mark would enable the long or readout sweep to traverse the row of information and readout would occur. The shorter sweep would again take place and the same procedure would be repeated. An advantage of the partial scan method is that it would decrease the bit rate to approximately half that of a full-scan method, since there are approximately half as many total scanning lines per scanning raster. One disadvantage would be that two separate horizontal sweep systems would be necessary. They could be achieved with special sweep circuit and yoke design that would add to the complexity of a system.

The third method is to use a vertical scan which would continue to move in its vertical path until it intercepted a sensing tab. The signal derived from this interception would be used to enable the horizontal sweep, and readout of the information would occur. This method has one advantage over the previous two in that the bit rate would be approximately one third that of the full-scan method, and also less than that of the partial scan. There are added disadvantages, however, not only because special sweep-circuit and yoke designs are needed, but also because the trace would be required to return to within a close tolerance of its initial starting point. This tolerance would necessarily depend upon the application in question. Also, the long-term drift associated with tube and component decay, plus variations in operating voltage, would present a problem. However, these last two methods are feasible and have been considered from the standpoint of lowering the bit rates in systems with rates of one megacycle or greater, so that lower frequency circuits may be employed. Some means of identifying or sensing the the center portion of each row of information must be considered. A small square bit, half the size of the information bits, could be located directly in front of each row of information. If this small bit were intercepted, it would serve to enable the readout equipment to sense the information in that particular row. Another method would be to have the rows separated by a space and to utilize the techniques employed in the system previously mentioned. This would, however, reduce the amount of information to some extent, depending on the spacing required. A third method would be to employ a stripe with tabs projecting in the horizontal direction in line with each row of information present. The signal derived from the stripe, plus the tab, would serve to enable the readout circuit and cause the information to be sampled.

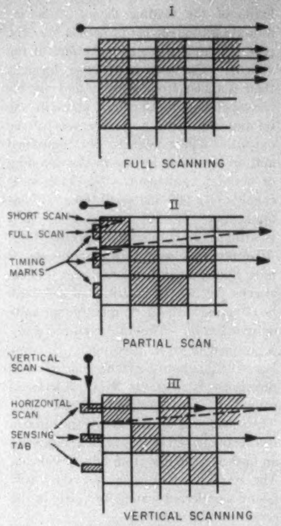

Fig. 5. Scanning patterns

Summary

The application of the type of equipment described may from the simple installation of code wheels attached to existing shafts on equipment, and camera with recording head, to the installation of nonloading, highly accurate (one part in 100,000) transducers with servo units and special timing generators. The film reader equipment may be designed simply to read the coded data and provide printed records, or it may include pictorial display by projection or by kinescope monitors remotely located. For data file systems, an automatic search feature may be provided, which on command, searches the film, frame by frame, until the desired information is located. Preliminary studies indicate that search of 40 frames per second of data, made up of 600 bits per frame, may be achieved with the use of techniques developed for existing machines. Even greater reading rates appear feasible with extensions of the existing methods.

The practical systems developed include a spot size of 10 by 10 mils, data rows of up to 40 bits, output rates of up to 200 kc, recording rates of 64 frames per second, with 90 bits per frame. Incandescent lamp recording has been used, and either cathode-ray tube or vidicon readers have been employed.

Bits of Information

A. S. ZAMANAKOS
NONMEMBER AIEE

Synopsis: The paper reviews the concepts of information, channel capacity, and equivocation. The probability of error is used to calculate the equivocation. It is then explained that by coding the original message or signal it is possible to incorporate into the coded message the error-detecting and error-correcting information. The requirements of an efficient code are stated, and the Shannon-Fano code cited as an example. The parity check is explained and the manner in which it makes use of the error-detecting and error-correcting information is illustrated.

THE FIRST STAGES of learning about a new field are usually fraught with difficulties of understanding and applying the various theorems and definitions. This paper will recount certain experiences in the process of becoming acquainted with communication theory, which is a subdivision of the broader field of information theory.

A measure of information was established by Hartley[1] and is defined by the equation

$$H' = \log N \tag{1}$$

where N is the number of signals, messages, symbols, or states available from a particular information source. If the base of the logarithm is equal to 2, then H' is in bits of information.

If the information source is an $m \times n$ matrix and each element of the matrix may assume L symbols, values, or levels, the measure of information is

$$H' = \log_2(L^{mn}) = mn \log_2 L \text{ bits} \tag{2}$$

A frame (or two fields) of a television picture is an example of such an information source; see Appendix I for a numerical example.

Equation 1 may be interpreted to mean that the frequency of occurrence of the various states which make up N is unknown; therefore they are all assumed to be equally probable. (It also happens that in this situation the information has been maximized.) If, on the other hand, something is known about the statistical nature of the information source, this must be taken into consideration. Assume that the simple probability (the appearance of one symbol or state, independent of the other symbols or states) $p(l_i)$, of each symbol L_i which the information source yields, is known. When these probabilities are applied to the matrix information source, and when mn is large, a particular symbol l_i will appear $mnp(l_i)$ times. Since the probabilities $p(l_i)$ are independent, each of the states represented by the various permutations of the mn symbols have the same probability of occurring. Therefore the probability of obtaining any state of the matrix (belonging to N) is

$$P_r = p(l_1)^{mnp(l_1)} p(l_2)^{mnp(l_2)} \dots p(l_L)^{mnp(l_L)} \tag{3}$$

and P_r is, for all purposes, a constant. Then $1/P_r$ is equal to the total number of states N in equation 1, see Appendix II. Substituting equation 3 into equation 1

$$\begin{aligned} H' &= \log_2(1/P_r) = -\log_2 P_r \\ &= -mn \sum_1 p(l_i) \log_2 p(l_i) \end{aligned} \tag{4}$$

and the information per matrix location or element is

$$H = \frac{H'}{mn} = -\sum_1^L p(l_i) \log_2 p(l_i) \tag{5}$$

Equation 5 was established by Shannon,[2] who called it the entropy of the information source.

If there is nothing to interfere with the communication of the output of the information source to some receiver,

$$H(x) = H(y) \tag{6}$$

where $H(x)$ is the entropy of the information source and $H(y)$ is the entropy of the receiver. This is a description of an ideal system. Because of thermal or resistor noise, it is certain that there will always be at least a minimum value of hindrance to any communication from source to receiver. Therefore, in place of the ideal situation described by equation 6, a definition is required of the joint entropy of the information source, the communication channel, and the receiver, as follows:

$$H(x,y) = H(x) + H_x(y) = H(y) + H_y(x) \tag{7}$$

The terms $H_x(y)$ and $H_y(x)$ are called conditional entropy or equivocation, and represent false information, i.e., $H_x(y)$ is a measure of the false information in the received information y, when the transmitted information is x; this is also true of $H_y(x)$ and y; see Appendix III.

When noise is apparent in the system, the simple probabilities introduced earlier are no longer applicable; instead, the joint and conditional probabilities, $p(x,y)$ and $p_x(y)$ or $p_y(x)$ must be employed. They are related as follows:

$$p(x,y) = p(x)p_x(y) = p(y)p_y(x) \tag{8}$$

As to the next step, it would appear reasonable to ask: "What is the rate at which we can transmit or communicate in the presence of noise?" According to Shannon the rate of transmission (of information) is equal to the entropy of the source minus the information lost due to noise:

$$R = H(x) - H_y(x) \tag{9}$$

In terms of reception

$$R = H(y) - H_x(y) \tag{10}$$

The maximum value R can assume is called the "channel capacity" and is designated by C:

$$C = \max[H(x) - H_y(x)] \tag{11}$$

In the noiseless case $H_y(x) = 0$ and C is evidently equal to $H(x)$ or $H(y)$, since $H(x) = H(y)$.

A value for C may be obtained in the noiseless case by using Shannon's original definition of channel capacity:

$$C = \lim_{T \to \infty} \frac{\log_2 N(T)}{T} \tag{12}$$

where T is the maximum duration of the signals which comprise $N(T)$. For a teletypewriter system, under noiseless conditions

$$N(T) = (2^5)^{nT} \tag{13}$$

where n is rate of teletypewriter (character) transmission per unit time; therefore

$$C = \lim_{T \to \infty} \frac{\log_2 (2^5)^{nT}}{T} = 5n \tag{14}$$

If thermal noise which may be present is accounted for,

$$\begin{aligned} C &= \lim_{T \to \infty} \frac{\log_2 [\sqrt{(1 + p/\mathfrak{N})}]^{2WT}}{T} \\ &= W \log_2(1 + p/\mathfrak{N}) = W \log_2(p + \mathfrak{N}) - W \log_2 \mathfrak{N} \\ &= H(p + \mathfrak{N}) - H(\mathfrak{N}) \end{aligned} \tag{15}$$

Paper 58-34, recommended by the AIEE Communication Theory Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2-7, 1958. Manuscript submitted April 2, 1957; made available for printing November 27, 1957.

A. S. Zamanakos is with the U. S. Naval Research Laboratory, Washington, D. C.

The author would like to express appreciation to S. F. George, consultant, Radar Division, Naval Research Laboratory, for his encouragement in this work.

Table I. Construction of Shannon-Fano Code

Example 1				Example 2			
Symbol No.	Probability	Code	Division	Symbol No.	Probability	Code	Division
1	1/4	0 0		1	1/4	0 0	
			(2)				(2)
2	1/8	0 1 0		2	1/4	0 1	
			(3)				(1)

where W is the system bandwidth, in cycles per second, $P/\mathfrak{N}$ is the ratio of the average signal and noise powers, and the terms $H(p+\mathfrak{N})$ and $H(\mathfrak{N})$ correspond to $H(y)$ and $H_x(y)$ of equation 10. The term $\sqrt{(1+P/\mathfrak{N})}$ is the number of distinguishable voltage levels and $2WT$ is the number of elements or the length sequence of signals. The product $2WT$ is also the number of independent samples (or amplitudes) required to describe a function of duration T and bandwidth W.

Some of these relations will now be applied to a communication system composed of a 5 by 5 transmitting matrix and a 5 by 5 receiving matrix. The 25 elements or locations of the transmitting or information source are assumed equally probable of selection for (sequential) transmission. Therefore

$$H(x)=\log_2 25=4.64 \text{ bits per location} \qquad (16)$$

Assume in the transmission of a sequence of n signals that there will be a total of e errors, and that the location of these errors is known. This means that, to correct each error, only the remaining 24 possible elements or symbols need be considered. This selection represents an entropy of $\log_2 24$. Since the sequence length is n and there are e errors, a total of $e \log_2 24$ bits of information, or an average of $e/n \log_2 24$ bits per symbol, are needed to correct the errors. From the definition of equivocation,

$$E_1=p_e \log_2 24 \qquad (17)$$

which is the equivocation per received symbol and where

$$p_e=\frac{e}{n} \qquad (18)$$

is the probability of error.

But if the location of the errors is unknown, additional information is needed in order to establish their location. Using p_e as the probability of error and q as the probability that the symbol is correct yields, from equation 3

$$P_r=p_e{}^{np_e}q^{nq} \qquad (19)$$

The average amount of information per symbol required to locate the errors is

$$E_2=-\frac{1}{n}\log_2 P_r$$

$$=-(p_e \log_2 p_e+q \log_2 q) \qquad (20)$$

Since entropy has the additive property, the total equivocation of the system per symbol is

$$E=E_1+E_2=-(p_e \log_2 p_e+q \log_2 q)+p_e \log_2 24 \qquad (21)$$

Equation 21 represents the amount of additional information per symbol required to locate and correct the received message. E may be calculated if certain signal shape and thermal noise are assumed; see Appendix IV for another example. The signal shape may be a prescribed pulse (or no-pulse) occurring at specified times.

The way to calculate the measure of information and equivocation of a noisy system has been considered. The next step is to consider the manner in which this error-detecting and error-correcting information may be conveyed or communicated. This is to be accomplished by the use of error-detecting and error-correcting codes. Such a technique is the "parity check" and is quite effective in systems employing binary coding: 0's and 1's, or pulse and no-pulse. The parity check method will be touched upon. A rigorous presentation may be found in the work of Hamming[3] and of Gilbert.[4] More complex codes have been proposed by Silverman and Balser,[5] and others.

But before proceeding let us just mention the efficiency aspects of coding. A measure of efficient coding[6] is one which yields for the different symbols l_i and corresponding durations t_i the most probable a priori density distribution, namely the following:

$$\frac{-\log_2 p(l_i)}{t_i}=\beta \text{ (a constant)} \qquad (22)$$

where $p(l_i)$ is the proportion of times that the symbol l_i appears in the message. Equation 22 is intuitively satisfying for it may be interpreted as follows: The time required to communicate a particular symbol shall be inversely proportional to its frequency of occurrence or appearance in the message. This criterion was closely approximated in establishing the Morse code since the frequently used letters were assigned the shortest symbols.

The Shannon-Fano code is an example of an efficient code.[7] In it the length of the code group, in binary digits, is set approximately equal to $-\log_2 p(l_i)$ where $p(l_i)$ is the probability of the symbol l_i. The code is simple to construct and is as follows: The symbols available at the information source are set down in a column of decreasing probability. The column is divided into two divisions, upper and lower, in such a manner that the sums of the probabilities of each division are approximately equal. Since it will not always be possible to make the sums of each of the two resulting divisions equal, it will be agreed in advance that the probability sum of the upper division will be greater than that of the lower. The sums resulting from the first division process will be equal to 1/2. The digit 0 is assigned as the first digit in the code group for all the symbols appearing in the upper half and the digit 1 is assigned as the first digit in the code group for all the symbols appearing in the lower half or division. The division process is repeated, but now the probability sums are equal to 1/4. Again, the digit 0 is assigned, but as the second digit in the code group, for all the symbols which appear in the upper half and the digit 1 for all those in the lower. This division process is repeated until there is a single member only in each division.

An essential property of the Shannon-Fano code is that no short code group can appear as the initial portion of a longer code group; thus a built-in code group recognition aid is provided. Table I is an illustration of this process.

To return to the subject of parity checks, the established rules (which appear to be standard) are: 1. A sequence of checking signals will be sent, along with the information signals, and together they will constitute a code group; the location of the checking signals is fixed; 2. Adding the information signals and the checking signals in a prescribed manner will yield an even-valued number; since binary digits are used, the sum must terminate in a zero, in other words, an even number of 1's.

An easy example to analyze would be to send one information signal A and two checking signals B and C, and to specify that

$$A+B=\text{even} \tag{23}$$

$$A+C=\text{even} \tag{24}$$

A would be correct under these conditions. Assume that there is only one error; then, if equations 23 and 24 are both odd, it is known that A as received is incorrect. If one equation is even and the second odd, then the checking signal associated with the odd sum is incorrect.

The appearance of two actual errors would lead to wrong conclusions. Fortunately, including one additional checking signal D would determine if two errors were present. The additional checking equation would be

$$A+D=\text{even} \tag{25}$$

For example, if $A=1$ and $B=1$, when all the information and checking signals should be equal to zero, the following would prevail:

$$1+1=\text{even } (=10) \tag{23A}$$

$$1+0=\text{odd } (=1) \tag{24A}$$

$$1+0=\text{odd } (=1) \tag{25A}$$

and it would be known that there were two errors, but their location would not be known.

Returning to the situation in which no more than a single error can occur in a sequence of message symbols, the error may be located if enough checking signals are employed. Using a large enough signal-to-noise ratio[8] would ensure that only a single error would be likely. If there are m information signals and k checking signals, $(m+k+1)$ situations may be described as: 1. all signals correct, or 2. one of the m information signals or one of the k checking signals incorrect. In general, if the total number of transmitted symbols (or signals), composed of information and checking signals, is equal to $m+k$, it is seen that there are L^{m+k} possible transmission states. Out of this number of states L^k represents the various states which the sequence of checking signals may assume. Because binary digits are used, and $L=2$, the relation

$$2^k \geq m+k+1 \tag{26}$$

must hold. The equality relation represents the most efficient checking procedure. But even with the equality condition it may be that unavoidably, more bits of checking information than necessary are being sent. For example, assume the following:

1. A zero has been received.
2. The probability that a zero was sent is $q_0=0.995$.
3. The probability that a 1 was sent is $pe_0=0.005$.

If a 1 was received, the probability that a 1 was sent is $q_1=0.995$ and that a zero was sent is $Pe_1=0.005$. The equivocation per symbol (using equation 37) is $H_y(x)=0.045$ bits per symbol. In this example, two bits of checking information are used; therefore 2/0.045, or almost 45 times more checking information, has been included than theoretically necessary.

If there are two information signals, m_1 and m_2, it is known from equation 26 that three checking signals, k_1, k_2 and k_3 must be employed. The checking sums, established before hand, would be

$$m_1+k_1=\text{even}$$
$$m_2+k_2=\text{even}$$
$$k_1+k_2+k_3=\text{even}$$

and it would be determined as to which of the five signals was incorrect or if they were all correct. The number of checking sums or equations is equal to the number of checking digits, see Appendix V.

Of course, this error-detecting and error-correcting process implies a certain disadvantage, usually an increase in system bandwidth when the coding characters are transmitted at a constant rate. For example, in a teletype system if a bandwidth W is required to transmit the five information signals, it is calculated, from equation 26, that at least four checking signals are required. Thus the code group is composed of nine signals. If it requires time

$$t_0=\frac{5}{2W}=\text{a constant} \tag{27}$$

to send the five information signals, then, in order to send the nine signals in the same length of time, i.e.,

$$t_0=\frac{9}{2}W' \tag{28}$$

the bandwidth required is

$$W'=\frac{9W}{5} \tag{29}$$

In other words, the bandwidth has been increased by a factor equal to the ratio of the number of signals in the code group to the number of information signals. This shortening of the signals renders the system more susceptible to errors (because of the increased bandwidth), and an increase in the signal-to-noise ratio may be required to offset this condition. An additional task will be to decide if this is too great a price to pay for relatively error-free communication.

Appendix I. Information Content of a Television Picture, Assuming Zero Redundancy

If the horizontal scan frequency is 15,750 cycles per second, the period is equal to 63.5 μsec (microseconds). The sync and blanking consume 10.3 μsec, leaving 53.2 μsec as the visible scanning time t_v, in a line or row. With a 4-megacycle bandwidth W, the shortest picture element in a line which may be distinguished is $1/2W$ seconds' duration. The number of visible elements in a line will then be $t_v/(1/2W)=425.6$. Ordinarily 40 lines are lost because of the time required for retracing and blanking between fields; therefore, only 485 out of 525 lines are active. Assume that there are eight levels of intensity or picture element brightness. Substituting the numbers into equation 1 yields

$$\begin{aligned} H' &= \log_2 (l^{mn}) \\ &= \log_2 (8^{525\times 485}) \\ &= 76{,}875 \text{ bits per picture} \end{aligned} \tag{30}$$

Appendix II

The question has been raised as to whether N (or $1/P_r$) actually approximates the total number N_T of matrices having mn elements. The following is offered as proof that it does.

Assume that the total number of matrices containing mn elements is N_T. Out of this number of matrices there will be N of them containing $mnp(l_1)$ symbols of type l_1, and $mnp(l_2)$ symbols of type l_2, and so on to symbol of type l_L. The probability a matrix belonging to the set N is $P_r'=N/N_T$ and the probability of obtaining a particular matrix from N_T but belonging to the set N is

$$\begin{aligned} P_r &= p(l_1)^{mnp(l_1)}\, p(l_2)^{mnp(l_2)} \ldots p(l_L)^{mnp(l_L)} \\ &= \prod_1^L p(l_i)^{mnp(l_i)} \end{aligned}$$

With the description of the matrices belonging to the N, the latter may be found, i.e.,

$$\begin{aligned} N &= \frac{(mn)!}{[mnp(l_1)]! \ldots [mnp(l_L)]!} \\ &= \frac{(mn)!}{\prod_1^L [mnp(l_i)]!} \end{aligned}$$

Now, for P_r', as a result of this,

$$P_r'=NP_r=\frac{(mn)!}{\prod_1^L [mnp(l_i)]!} \prod_1^L p(l_i)^{mnp(l_i)}$$

Taking the logarithm and using Stirling's approximation yields

$$\log P_r' = \log (mn)! - \log \prod_1^L [mnp(l_i)]! + \log \prod_1^L p(l_i)^{mnp(l_i)} \cong$$

$$(mn)\log(mn)-\Sigma[mnp(l_i)]\times$$
$$\log[mnp(l_i)]+\Sigma[mnp(l_i)]\times$$
$$\log p(l_i)\cong(mn)\log(mn)-$$
$$(mn)\log(mn)\Sigma p(l_i)-(mn)\Sigma p(l_i)\times$$
$$\log p(l_i)+(mn)\Sigma p(l_i)\log p(l_i)\cong 0$$

Therefore $P_r'=NP_r\cong 1$ or $N\cong 1/P_r$ and, because $P_r'=N/N_T$, it follows that $P_r=1/N_T$. Thus $N\cong N_T$, which was to be proved. The matrices dealt with here are of the type that Shannon specified in his theorem 3.[3]

Appendix III. Equivocation of $H_x(y)$

If $H(x,y)$ represents the entropy of a joint event, the transmission of x and the reception of y, and from it is subtracted the entropy at the transmitter, there remains the undesired entropy due to noise or interference. This undesired entropy is, of course, false information, and will be called equivocation. To equate,

$$\begin{aligned}H(x,y)-H(x)&=-\sum_{i,j}p(i,j)\log p(i,j)+\\&\qquad\sum p(i,j)\log p(i)\\&=-\left[\sum_{i,j}p(i,j)\log\frac{p(i,j)}{p(i)}\right]\\&=-\left[\sum_{i,j}p(i,j)\log p_i(j)\right]\\&=H_x(y)\end{aligned}\tag{31}$$

The following relations have been used:

$$\sum_j p(i,j)=p(i)\tag{32}$$

$$p(i,j)=p(i)p_i(j)\tag{33}$$

Appendix IV. Probability of Error[8] and Equivocation

A communication system (bandwidth W) is sampled at the prescribed intervals. The system employs pulses whose maximum amplitude at the prescribed sampling points is equal to v_0 if there is no noise present. But since thermal noise will be present a signal threshold must be established, which will be equal to $v_0/2$; i.e., if the sample value exceeds $v_0/2$ it may be said that a pulse is present; if the sample value is less than $v_0/2$ it may be said that no pulse is present. Since only the presence of thermal noise and positive-valued pulses at the sampling points is assumed, the probability that the noise will exceed $v_0/2$ is

$$p_e=\frac{1}{\sigma\sqrt{2\pi}}\int_{v_0/2}^{\infty}\epsilon^{-\frac{t^2}{2\sigma^2}}\,dt\tag{34}$$

where the variance σ^2 is the mean noise power. Making a change of variable, $\lambda=t/\sigma$ yields

$$p_e=\frac{1}{\sqrt{2\pi}}\int_{v_0/2\sigma}^{\infty}\epsilon^{-\frac{\lambda^2}{2}}\,d\lambda\tag{35}$$

As a result of this change of variable the lower limit of integration is a signal-to-noise ratio which may be put in the form

$$\frac{v_0^2}{\sigma^2}=\frac{p_s}{\mathfrak{N}}\tag{36}$$

where p_s is the signal pulse power and $\mathfrak{N}$ is the noise power.

For example, if the signal-to-noise power ratio, $p_s/\mathfrak{N}$ is 22 decibels, then $v_0/2\sigma=6.294$. In the Work Projects Administration Tables of Probability Integrals,[9] a value is given of $1.59\times1.59\times10^{-10}$ for the probability of error p_e. The complement of p_e is $q=1-p_e$, which is the probability that the symbol is correct. Using the general equation of total equivocation

$$E=-(p_e\log_2 p_e+q\log_2 q)+p_e\log_2(N-1)\tag{37}$$

determines the additional information (check signals) required to correct the errors. N in equation 37 has the same significance as in equation 1. Equation 37 also reveals one of the advantages of using a binary signal (or information) transmission system. This advantage is that $p_e\log(N-1)$ is equal to zero since $N=2$. When the total equivocation is decreased, it is therefore unnecessary to send as much additional information.

Appendix V. General Process

The process used to determine the checking sums was one of deduction, i.e., first by using k checking sums the correctness of the first information signal is established; then by taking $(k-1)$ checking sums, the correctness of a second information signal can be determined. This

k

step is performed $(k-1)$ times where

$$\binom{k}{r}=\frac{k(k-1)\ldots(k-r+1)}{r!},\ \binom{k}{0}=\binom{k}{k}=1$$

and the range of the index is $0\leq r\leq k$. Then $(k-2)$ sums, etc., are taken. In the foregoing, similarity is noticeable to the problem of algebra concerning the number of ways in which k elements (in this instance, checking sums) may be grouped, i.e., k at a time, $(k-1)$ at a time, $(k-2)$ at a time, etc. Thus

$$\binom{k}{0}+\binom{k}{1}+\ldots+\binom{k}{r}+\ldots+\binom{k}{k}=N\tag{38}$$

as the total number of different groups (combinations). Next, it may be recalled from the binomial theorem that

$$(a+b)^k=\binom{k}{0}a^k+\binom{k}{1}a^{k-1}b+\ldots+\binom{k}{r}a^{k-r}b^r+\ldots+\binom{k}{k}b^k\tag{39}$$

and writing $a=b=1$ yields

$$2^k=\binom{k}{0}+\binom{k}{1}+\ldots+\binom{k}{r}+\ldots+\binom{k}{k}=N\tag{40}$$

or

$$2^k=1+k+\ldots+\binom{k}{r}+\ldots+1\tag{41}$$

Using the equality sign in equation 26 and solving from m yields

$$m=2^k-k-1\tag{42}$$

Combining equations 41 and 42 yields

$$m=2^k-k-1=1+k+\ldots+\binom{k}{r}+\ldots+\binom{k}{k-2}\tag{43}$$

Recalling the order in which the correctness of the information signals was established, equation 43 may be interpreted to mean that the k checking sums establish the correctness of the first information signal, and that

$\binom{k}{k-1}$ checking sums

establish the correctness of the next k information signals as indicated by the second term on the right-hand side of equation 43; or, in general, the $(r+1)$ term on the right-hand side of equation 43 determines the correctness of the next

$\binom{k}{r}$ information signals.

Appendix VI. Hamming Codes

Single-Error Detection

A single error may be detected by adding a (checking) binary digit to the message sequence of binary digits so that there are an even number of 1's in the resulting code group. This is called an even parity check. The combination of the information and checking digits is called a code group.

Single-Error Correction

The number of k checking digits required is determined by the relation $2^k\geq m+k+1$, where m is the number of message digits. Hamming determined the checking digit locations in the code group to be 1, 2, 4, 8, ..., numbered from the left of the code group. The first parity sum checks locations 1, 3, 5, 7, ...; the second checks locations 2, 3, 6, 7, ...; the third checks locations 4, 5, 6, 7, ...; Notice that the binary representations of the locations checked by the ith parity sum have a 1 in the ith location. The numbering in this instance starts at the right of the binary digit representation.

If the first parity check fails, a 1 is recorded (or a zero if it is satisfied). If the second parity sum fails, a 1 is again recorded but placed to the left of the binary digit recorded from the previous check. This process is performed k times and therefore yields a k-digit "checking number." The decimal representation of the checking number is the location of the (single) error in the code group. For example, if the number is zero it means that no error is present. If the number is 3 (011 in binary form) it means that the binary digit in location 3 of the code group is in error, etc.

Single-Error Correcting and Double-Error Detection

This process is accomplished by adding one more checking digit to the code group used in simple-error correction, and corresponds to location number $(m+k+1)$. The additional parity check which is introduced requires that the new code group (composed of $(m+k+1)$ binary digits) be even.

The following cases may exist:

1. No error. All the parity checks are satisfied.

2. Single error. The last parity check (which is applied to the new code group) fails, and the checking number obtained by single-error correction locates the error. The checking number 0 means that the last location is in error.

3. Two errors. The last parity check is satisfied but the checking number obtained by single-error correction is not equal to zero.

Study of Return Losses on Loaded Trunk Cables and Methods Taken to Improve Them

G. H. SPEAKE
ASSOCIATE MEMBER AIEE

RETURN loss as a measure of a circuit's uniformness has been used in the Telephone Industry for many years. It usually determines the amount of gain which may be introduced into a circuit before encountering undesirable conditions of echo or singing. While the toll plant, or long distance circuits, have been of primary interest, today's transmission objectives tend to emphasize the need for accurate analysis of all trunk cables with a view toward their improvement. This paper will review briefly the meaning of return loss, and attempt to acquaint the reader with some of the practical factors encountered in analyzing and improving the return loss of loaded trunk cables.

Return Loss

IMPEDANCE IRREGULARITIES

The return loss at an irregularity in a loaded cable has been defined in Bell System Practices and other literature as the transmission loss corresponding to the absolute ratio of the current, that would flow if no irregularity were present, to the amount of current reflected by the irregularity. A determination of its value at the point of irregularity involves a consideration of three impedances. If Z_{ox} is the iterative impedance to the left of a point, $Z_o\,(1-x)$ the iterative impedance to the right of the point, and Z_t the impedance looking through the irregularity, the return loss in db (decibels) is given by

$$RL = 20\log_{10}\frac{Z_{ox}+Z_t}{Z_{ox}-Z_t} + 20\log_{10}\frac{Z_0(1-x)+Z_t}{Z_{ox}+Z_t} \quad (1)$$

For irregularities located at mid-coil or mid-section, the second term reduces to zero, since the iterative impedance to the left and right are equal. For all practical work, the second term is usually ignored with negligible error. The return loss as determined may be referred to some other point in the circuit by adding twice the value of the intervening transmission loss.

STRUCTURAL IRREGULARITIES

While it is impractical to calculate the expected structural return loss of an individual cable pair before installation, it is feasible to determine a value of return loss which should be equaled or exceeded by any stated percentage of pair within a cable sheath, or a group for which the controlling parameters are known. The procedure derived by Crisson in 1925 is in use today.[1] For any loaded cable

$$S_1 = S_H + S_W + S_F - S_A + (S_n - S) \quad (2)$$

S_1 is the return loss in db which, it is expected, the selected percentage of pairs will equal or exceed, S_H is known as the irregularity function, S_W the frequency function, S_F the distribution function, S_A the attenuation function, and $(S_n - S)$ is a correction applicable to circuits which are not long enough to act as infinite lines.

In equation 2, S_H is primarily the factor which affects S_1. It is equal to 20 $\log_{10} 1/H$ where H is the square root of the sum of the inductance deviation squared plus the capacitance deviation squared. It is expected that the reader is either familiar with this concept or that the reference will be consulted for a thorough discussion.

CAUSE OF IRREGULARITIES

Equations 1 and 2 are presented here to show that the return loss of the loaded trunk is dependent upon the structural uniformness of the cable, and any additional impedance irregularities which may exist. From equation 2, it is seen that structural irregularities are dependent on the variations in manufacture, placing, and splicing of the cable, and also on the variations in the manufacture and spacing of the loading coils. Impedance mismatches which occur in trunks composed of different-gauge cable, while not considered in equation 2, are irregularities,

and could be expected to affect the return loss. From the practical standpoint, the operating engineer has the most control over placing and splicing of particular cables and the spacing of loading coils. Of course, he also may choose proper terminations to reduce impedance mismatches at terminal points.

Existing Plant

TERMINATIONS

Although this paper is primarily concerned with trunk cable, the termination necessary to complete a circuit must of course be considered, since equations 1 and 2 show that the total return loss is dependent upon the terminal impedance match and the structural uniformness of the cable. The signalling, idle circuit, and talking or through conditions must be considered separately, because the proper operation of the circuit may require different terminations in each of these cases. For the talking or through conditions, the circuit termination normally consists of a repeating coil or transformer, the exchange loop cable, and the subscriber instrument. The loop cable plant generally consists of the most economical combinations of cable gauges, chosen within the limits of resistance design,[2] which combinations naturally present different impedances for different loops. Therefore, the choice of a transformer to match the trunk to the loop usually must be based on some average impedance value. The impedance of the telephone set is also fixed by design at an average value. For those trunks which are equipped with repeaters or gain devices, idle circuit terminations or a repeater disabler may be provided for the idle circuit or signalling conditions.

LOADED TRUNKS

The type of cable normally used for trunk circuits consists of paired conductors having various lengths of twist and a mutual capacitance of approximately 0.082 microfarad per mile. This is generally referred to as "exchange grade" in comparison with a toll grade or quadded conductor cable. The type and spacing of loading coils are recorded, but available records usually give little or no information about details of splicing or manufacture irregularities and tolerances. Therefore, for calculations, it is necessary to assume values for the unknown factors based on average figures and a knowledge of the splicing procedures which have usually been employed. "Bell System Practices" gives 0.007 as the standard deviation for 88-

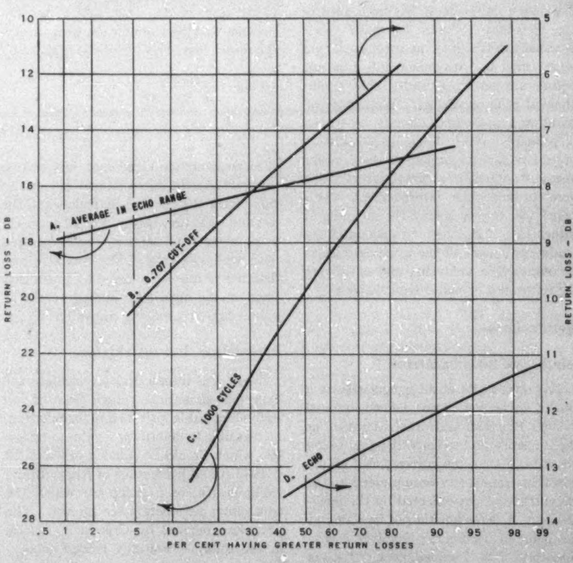

Fig. 3. Distribution of return losses for Cable 1

millihenry coils, and 0.027 as the loading-section capacitance deviation for exchange grade cable loaded at 6,000-foot intervals without deviation test splicing or reel allocation. The inductance deviation due to loading-coil spacing may vary from 0.005 to 0.03 or more. Thus the return loss may be greatly influenced by coil spacing irregularities.

A survey has shown that, in one metropolitan area having approximately 38,000 trunk pairs, 22% of the total are composed of cable pairs of two or more gauges. Trunk pairs in this case are understood to be those pairs between main frame terminations. Since these pairs are sometimes strapped together at several main frames in order to make up a complete trunk, at least 22% of the total trunks must have a split-gauge makeup. Also, approximately 48% of the trunk pairs were in the same cable sheath as pairs used for exchange loops. Although this situation does not affect the return loss of the trunks, it does make it difficult to determine the return loss distribution of the cable by measurements, because exchange loops are not readily available for testing.

Improvement Considerations

General

Because earlier transmission objectives for most trunks were from 8 to 10 db, the return loss was usually not very critical. However, with today's objectives of via net loss to 6 db, and even in some instances of zero loss or a net gain, the trunk cable must in some cases meet the same stringent requirements as an intertoll trunk. Preliminary surveys show that many of the existing trunk cable pairs do not have high enough return loss to support the gain necessary even for a 6-db trunk. Where the percentage of existing pairs that are capable of supporting the required gain is insufficient, it will eventually be necessary either to place new cable, spliced for a high return loss, or to improve the return loss of the existing pairs.

Although it is usually rather difficult and expensive to apply available methods of improvement to working cables, there are several methods which, if properly applied, should result in a satisfactory return loss for cable of the type normally used. The expected return loss for various conditions may be calculated, and the most economical choice of improvement methods which will produce the desired results may be determined. Costs may vary considerably, depending on the particular situation.

As some areas have not required acceptance tests on loaded trunk cables in the past, it may be advisable before attempting any improvement of an existing cable first to determine whether some trouble condition, such as a missing loading coil or bridged tap, is contributing to a poor return loss. Any such condition should of course be cleared before proceeding with improvement plans.

For improvement, the loading coils may be more accurately spaced, the cable may be randomed, or capacitance deviation test spliced in various lengths, solid gauge pairs may be provided, and all splices soldered. Also, building out of loading sections and end sections with stub cable or commercial-type capacitors may be necessary. In addition, impedance compensators may be used at terminal points.

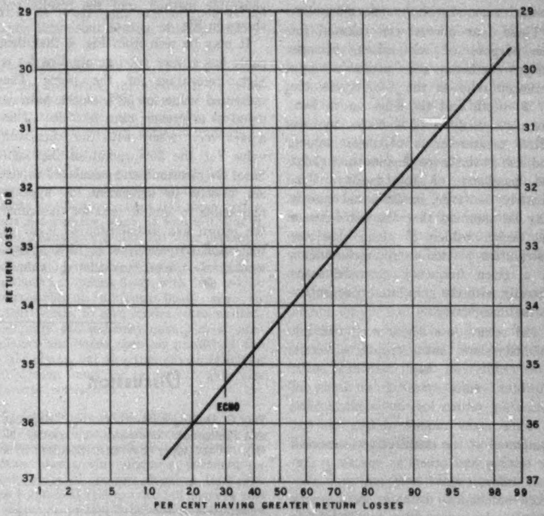

Fig. 4. Distribution of return losses for Cable 2

Other methods may also suggest themselves in particular cases. For example, it was found necessary in one instance to rework a small, 51-pair 22-gauge cable about 10 miles in length which had been hurriedly spliced in order to meet a service date. The cable was reterminated in a jack field, and patching cords were provided to maintain service during the splicing operations. The capacitance of each pair in each loading section was measured, and then all pairs were built out with commercial-type capacitors to a value equal to the highest capacitance found. This sufficiently improved the structural uniformness so that the repeaters could be satisfactorily operated.

Example. Cable 1

Recently return loss measurements were made on a loaded trunk cable which had a split-gauge makeup and a rather poor loading layout. This cable was placed during 1949 without regard to any special splicing procedures. The cable makeup and other pertinent data are shown in Fig. 1.

Fig. 2 is a block diagram of the testing arrangement and the equipment which was set up at the main frames. The precision balancing and terminating networks were chosen on the basis of the most predominant gauge, and were built out for the best return loss. This usually means building out the far end to a full loading section, and the near or measuring end to a matching section. A Hewlett-Packard oscillator was used as source power for the single-frequency measurements. Echo return loss measurements were made by replacing the oscillator with a Western Electric 201-*A* noise generator equipped with a 455-*B* network which simulates the output of an *F1* transmitter energized by a typical male voice. The *2B* noise-measuring set with *F1A* weighting was used as the indicating instrument. It was found necessary to use the *2B* set because there was insufficient gain available to utilize a vacuum tube voltmeter.

Measurements were made at 500-cycle intervals in the echo band from 500 to 2,500 cycles, and the results for each pair were averaged and plotted as curve *A* of Fig. 3. Curve *B* of Fig. 3 shows the results at 0.707 of the cutoff frequency, and curve *C* shows the results at 1,000 cycles. Curve *D* is the echo return loss as measured with the noise generator.

These four curves were plotted for the purpose of comparison, because design methods and available data variously refer to the 1,000 cycle, the 0.707 cutoff, and the echo return loss. Complete analysis of a cable thus requires measurements of these values, and also at single frequencies throughout the passband of the facility. Fortunately, however, in the usual case it may be assumed that the cable meets the design values, provided that the distribution plotted from measurements at a given frequency compare satisfactorily with the calculated distribution at that frequency.

The return loss distribution will not definitely show that a repeater will work satisfactorily on any individual pair. However, since present methods of measuring return loss on working pairs in some areas require setting up test equipment at the main frames, two men for testing, and others to operate make-busy relays, these tests are expensive. More economical methods usually may be utilized to determine the suitability of individual pairs, once it has been determined that the cable meets the design requirements.

The return loss as shown by Fig. 3 is generally poor, and is about 5 db less than expected. As precision networks are not available for exact matching of split-gauge trunks, some error is likely. It is also possible that a loading coil be missing or that some other trouble exists. No attempt has been made to determine all the factors which may be contributing to the poor return loss of this particular cable, because it was picked at random from a large number of cables in a metropolitan area, and the curves of Fig. 3 were plotted to show the return loss as found, as an illustration of what might be expected of existing cables. The split-gauge makeup may also be partly responsible. Whatever the cause, if the results as shown in Fig. 3 prove to be typical for the older split-gauge cable with poor loading layouts, many existing trunk cables may be unsuitable for economical repeater operation.

EXAMPLE. CABLE 2

This cable was placed in about 750-foot lengths, and each unit or group of pairs within the sheath was random spliced at the points where the sections were joined. The loading layout, with a calculated 0.01 coil-spacing deviation, was considered good. Echo return loss measurements were made with the 201-*A* noise generator method, and the results are shown in Fig. 4.

It may be seen from Fig. 4 that this cable has a very good return loss for a high percentage of the pairs. The measured value for 50% of the pairs is equal to or greater than 34.2 db. This agrees very closely with the calculated value for the 50% point of 34.4 db. Since the measured and calculated values are closely in agreement, it appears reasonable to assume that for this cable the return loss distribution at 0.707 of the cutoff frequency, or at 1,000 cycles, would also meet calculated values. This, of course, may not be true in all cases, as irregularities may cause rather sharp peaks and valleys for different frequencies.

Conclusions

It is possible that many existing loaded trunk cables have poor return losses, and thus must be improved or replaced in order to meet today's transmission objectives. The percentage of pairs having low return loss may be determined by calculation and by measurements for any frequency, or for the echo band, and the return loss may be increased to a satisfactory value by various existing methods.

The return loss distribution for newly placed cables may be plotted from acceptance tests. Any required improvements should be made before placing the cable in service.

Discussion

Flay G. Dellinger (Southern Bell Telephone and Telegraph Company, Charlotte, N. C.): The paper by Mr. Speake is a timely one and should stimulate thinking among people who are concerned with the problem of adequate return losses on loaded trunk cables.

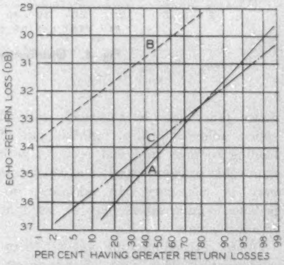

Fig. 5. A—Data from paper by G. H. Speake. Cable 2, 4.5 miles, 19-gauge
B—Trunk cable make-up, Charlotte, N. C. 3.82 miles, 19-gauge HC H-88, 0.90 mile, 22 gauge HC H-88, no capacitance deviation test splicing
C—Trunk cable make-up Charlotte, N. C. 5.14 miles, 22-gauge HC H-88, 437 pairs. No capacitance deviation test splicing

It should be apparent that the design and testing of loaded trunking cables have been handled very loosely in the past. Today, with our via net loss transmission objectives, our so-called exchange loaded trunking cables obviously must meet the same requirements from a return loss standpoint as those of a loaded toll cable. Further, there seem to be wide differences of opinion as to what type of test determines return loss. For example, is it necessary to make both echo return loss tests and singing-point tests? A standard Bell System practice for acceptance tests on trunking cables, I believe, would be most helpful to the Bell Telephone operating companies.

Fig. 5 indicates data taken on trunking cables in the North Carolina area as compared with the Cable 2 results given in Mr. Speake's paper.

G. H. Speake. The author is in full agreement with Mr. Dellinger's comments, which indicate that close attention to design and testing of loaded trunk cables is essential for today's transmission objectives. Also, Fig. 5, submitted by Mr. Dellinger, gives return losses on loaded trunk cables in the North Carolina area which are in general agreement with the author's experience.

A Basis for Transmission Performance Objectives in a Telephone Communication System

W. K. MacADAM
MEMBER AIEE

IN ANY extensive telephone system, certain objectives and controls must be set up to provide and maintain satisfactory performance. This control of quality is as important in communication service as in manufacturing. Rather than stemming from an engineer's dream or a mathematical formula, quality is essentially a user's impression of the product. There is danger, therefore, in measuring it in terms of somewhat arbitrary physical limits. There is danger, too, in not recognizing what lies behind the objectives and the effects on the user when these are not met.

Progress and improved living standards demand continually improving physical performance to maintain the same degree of quality from the customers' viewpoint. In some ways decibels (db) depreciate just like dollars. Hence the importance of not adopting a physical measurement of noise, volume, distortion, for example, and holding it sacred and unchanged throughout the years.

The evaluation of service performance and customer desires has been carried out more or less continuously in the telephone industry since its early days. However, recent subjective tests of received volume have added to the knowledge, particularly with regard to the higher levels. Such information permits the study of reactions to volumes ranging from excessive to inadequate. With this spread in data, the communications product can be analyzed from the viewpoint of preference rather than tolerance. Exposition of the new volume preferences and the derivation of corresponding transmission loss objectives are the main purposes of this paper.

The Service Package

There is no hesitation in naming "service" as the major product of a telephone communication system. Before measuring its quality, it is worthwhile to review briefly what this term includes.

The customer-oriented telephone service package can be divided into four parts, all of which are essential to a complete communications product. Stated in one sentence:

> A customer expects the right features, when he needs them, and as long as he needs them—but always with satisfactory quality.

The Right Features

In the first place, the user must be given the *kind* of service he wants, the type, the color, the shape, the operating features needed in his modern home or business.

When He Needs Them

The second part of the service job is to give the user telephone service *when* he needs it. Not only does this mean giving him a telephone when he wants it, but it also means giving him dial tone promptly when he lifts his receiver. It means that he should get through to his destination without a switching delay, with little chance of receiving an "all trunks busy" tone. In other words, to give service when wanted, not only are sufficient quantities of telephones and voice channels needed at the right places, but also appropriate switching equipment must be present to give him prompt connection.

As Long as He Needs Them

The third component of service is giving the customer service *without interruption*. In other words, this places a premium on continuity of service; freedom from line or equipment failure. To fall short in this respect is to fail to give him a complete service package.

With Satisfactory Quality

The fourth and by no means least of the components of service is the one of primary interest in this paper. This is *transmission*, the quality of the product the customer receives. By this is meant the volume, the fidelity, and the freedom from disturbance that make up a quality communication product.

The first three aspects of the service job give the telephone customer the features he wants and put him in a position where he can carry on communication. Transmission, the fourth side of service, actually is a measure of the product that is finally delivered. With much of the personal contact with operators gone as the result of customer dialing, telephone users judge performance more and more by the quality of the product they receive and less from their reaction to "the voice with the smile." It is significant to realize that, more and more, a customer's main contact with a telephone company is through the receiver of his telephone and the bill he receives every month. Putting both of these together, he will judge the company by what he actually gets for the money he spends. Quality control of the product is a way of seeing that he gets his money's worth.

"Quality of service" is a state of mind of the customer and not any technical measurement. Consequently, this state of mind will change and will be affected by all four of the components noted. As much dissatisfaction can result from a succession of minor annoyances as from a single major service failure. This is why consistently inferior quality is such a subtle danger; why good service one minute and poor the next builds up a sensitivity to contrast. This state of mind is reflected not only in the customer's opinion of the company in its ability to provide a communication channel, but also, rightly or wrongly, in his opinions regarding the company's financial soundness, for example, or whether it is a good place to work, whether it is efficient or a credit to the community.

Although there are a number of transmission effects that make up quality, one of particular interest is volume, since it relates to transmission loss objectives in the telephone plant. For this reason this paper will deal primarily with volume and loss objectives.

Volume by the Foot

As a starting point it is desirable first to obtain some physical idea of how telephone listeners react to various volumes. It is convenient to express relative ease of conversation in terms of an equivalent separation between talkers under more or less reflection-free conditions such as an open field, for example. This device has been used at times in the past.

Table I shows how average ease of conversation has improved over the years for typical telephone calls. It is based on extrapolation of comparative observations made in an open field by engineers from the American Telephone and Telegraph Company and Bell Laboratories in

---

Paper 58-59, recommended by the AIEE Wire Communication Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted October 11, 1957; made available for printing November 7, 1957.

W. K. MacAdam is with the American Telephone and Telegraph Company, New York, N. Y.

1939. The comparative variation with time is probably more accurate than the absolute values. From Table I it may be seen that 35 years ago for intercity calls, customers conversed as though they were 70 or 80 feet apart. For the trunked interlocal calls this "separation" might have been in the neighborhood of 40 or 45 feet. Twenty-five years ago, the average long-distance call dropped to about 35-foot separation with 25 feet for the interlocal calls. In the more recent past, the long-distance service improved to the point that the average toll call was equivalent to conversation at 15 feet with the local call dropping to 10 or 12 feet. Further recent improvement has brought the present-day picture for combined toll and local interoffice calls to an average of about 6 feet. Averages are deceiving, for the spread is quite great as a result of distributions in loop and trunk losses. The average is no consolation to the man receiving poor service on an individual call, particularly if he makes this call to one particular destination every day.

All this shows that quality standards are moving forward. When present performance is measured against listeners' preferences, it is not unusual to find there is still work to be done even if design objectives for new plant are kept up to date. A fixed gun setting is useless on a moving target. The difference between existing plant performance and present objectives is largely the result of not bringing old plant up to date. To some degree it is also caused by failing to get new plant installed and operating according to design.

What the Customer Wants

The first step needed in developing objectives is to find what quality of transmission the customer really wants. What should be the basis for service aims: complaints, tolerance, general satisfaction, or preference? Is there a demand for good service even if it costs somewhat more than poor service? Will poor service be tolerated under anything but emergency conditions? More fundamentally still, one is faced with the question: "What is 'good' and what is 'poor'?"

Table I. How Bringing Customers Closer Together Is a Continuing Job

When	Distance in Air, Feet: Intercity	Distance in Air, Feet: Trunked Local
35 years ago	70–80	40–45
25 years ago	35	25
Recently	15	10–12
Now	6 feet average	

Notes:

1. Weighted for bandwidth, sidetone, etc.
2. Individual calls may differ considerably from values shown.

Operating from complaints alone would emphasize objectives based only on what the customer will tolerate. This is like "Excellent" ratings comes at higher volumes (or lower circuit losses) than the valley for "Poor" ratings. This is caused by fewer "Good" (loud) ratings compared with "Good" (low). People seem to be so happy with high volumes that they rate them "Excellent" up to the point that their ears tingle and they begin to drop the rating into the "Poor" range or worse. At slightly lower volumes there is a larger range where many of the calls are either "Excellent," "Good," or "Fair," but very few "Poor."

Here is where a little judgment must be exercised to consider the economy and the effect on the telephone bill. At the high volume levels, at the peak of the "Excellent" ratings which were made without cost consideration, the user is fairly luxuriating in volume. He figuratively has his furnace on full, his windows open, and the gas meter by-passed. It is necessary to come down to earth at this point and look for prudent comfort and not princely elegance. This means swinging sights away from the peak of "Excellent" toward "Good" (low volume) but keeping "Poor" at a minimum.

There is another factor that must be kept in mind in setting design sights. Over-all service objectives must include the combined effect of design plus occasional troubles which produce poor volume or circuit failure. Telephone users do not worry as to whether their volume difficulties were caused by design weakness, component failure, poor adjustment, or a wet cable. They are just as unhappy in any case. Hope is always present that the millennium will come, that all plant will become trouble-free and will be kept in perfect adjustment. Even with all the attention engineering and maintenance people are giving this problem, these sources of low or nonexistent volume will continue for some time. Perfection is not necessarily the best over-all economic solution here any more than in the case of design. Consequently, to make due allowances for these sources of difficulty, even tighter reins must be placed on average design objectives to keep the over-all service in check. Allowing for an occasional missed target is similar to the philosophy of the taxi driver who said, "Twenty-five cents is my average tip but there ain't very many that gives the average."

With these considerations in mind, and recognizing that, for short hauls, volume still costs the telephone company and its customers something, design objectives might be set something like this:

Negligible number of calls rated *poor* because of design.

No more than about 5% rated *fair.*

The balance, *good* or *excellent.*

From Fig. 1 it is seen that this corresponds to the line marked "present objective" with an average trunk loss distribution of about 4 db. This is the current goal in the Bell System for trunked calls. To obtain this average of 4 db, total trunk losses should be controlled so that they range, say, between 2 and 6 db, assuming typical loop loss conditions.

In the future, when carrier becomes economical for shorter lengths, and impedances are under better control higher volumes will be available at practically no additional cost and further improvement will be possible. Nevertheless, it is equally certain that the future will bring preferences for still higher volumes. Probably more important still will be a trend toward lower talker volumes as the users become accustomed to the feeling of nearness to the other party. All this means future requirements for still lower trunk losses. In the ultimate, the objective must approach zero loss. From there on it must be lower loop loss, for the following reason.

Loss Reduction: Loops Versus Trunks

Controlling volumes means essentially, controlling the over-all loss between lips and ear. It is important, however, to apportion it properly over the various types of plant. This cannot be done just any way. The allocation must consider the effect on service, the relative usage of loops and trunks, and the cost and quantities involved, with, at the same time, future possibilities in sight. As accident prevention based only on a count of mortalities. Actually, to give satisfactory service in all respects, it is important to know what the user prefers and what he needs, and not just what he will barely stand.

Subjective tests by Reier and Coolidge at the Bell Telephone Laboratories have developed considerable data on received volume preferences in telephone conversations. For a given volume, several thousand observations were made with a variety of typical listeners. Volumes were rated by these listeners in several

Vol.
Pt. 1
1958

categories such as "Excellent," "Good," "Fair," "Poor," etc. Both appraisal and comparison tests were made in the range between "Intolerably Loud" and "Could Not Understand." From these data a family of curves was derived showing, for any particular received volume, the per cent of listeners that would rate this volume as "Good," "Excellent," etc.

Recently the Reier and Coolidge data were used as a basis for evaluating listener preferences under various circuit loss conditions. This was done by determining the distribution of received volumes which results from combining typical talker volume distributions with various trunk and loop loss distributions. Fig. 1 is the result of this statistical combination, considering trunked calls of any type. It shows how these trunked calls would be rated by a typical variety of customers for clusters of trunk circuit losses having different average values. The relationship between effective loop loss and volume loss is not a straightforward adjustment since it depends on frequency reponse, noises, and other factors. Although this relationship is still under study, the curves were developed using Reier's data of several years past.

Since Fig. 1 is used primarily to study trunk losses, the preferences are plotted in terms of various trunk loss averages for a constant typical cluster of loop losses. This assumes a fixed loop loss distribution with spread and average such as frequently encountered. If the average loop losses differ from those assumed, a compensating (−db or +db) change must be made in the trunk loss averages read on the horizontal scale. Care must be taken not to consider the curves as typical probability curves since the horizontal scale is in terms of averages and not specific individual losses.

Setting the Thermostat

Equipped with information on the customer's volume preferences, and some idea of what he thinks quality is worth, the next job is to set design objectives. This is not a matter of blindly increasing the gain. Adjusting volumes on telephone circuits is somewhat like setting the home thermostat in cold weather. Volumes can be too high or low for comfort, just as in the case of home temperature. On the average, high volumes are more costly, just as is the fuel bill for a high thermostat setting. Of course, where carrier proves in, this added volume cost is slight.

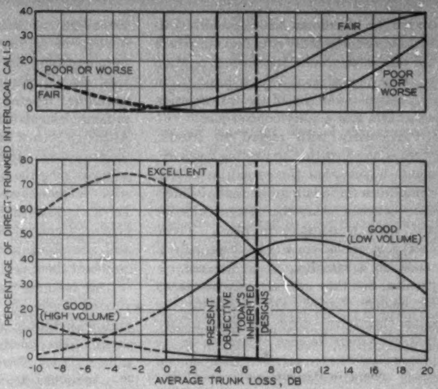
Increased temperature brings increased comfort only when the house is cold.

Fig. 1. Customer rating of transmission; trunked calls

Assuming standard deviation of trunks = 2 db

Assuming standard deviation of loops = 1.8 db

Assuming average of loops = −4 db effective



Likewise, higher volumes mean greater satisfaction only when normal levels are on the low side. At times in the volume case, not only is the "temperature" low, but past designs have set the thermostat below the present-day comfort level.

With reference to temperature preferences, some want it cool while others prefer it warm. Because of this spread, combined with the up and down variations in the heating system itself, there is only a comparatively narrow range left for the setting before someone becomes dissatisfied. The same is true for volumes. For any specific average trunk loss, some calls will be made over short trunks or loops to people who are sensitive to loud volumes. Likewise, there will be some calls which encounter more than average loss and will involve people who dislike low volumes. The net result is a very large spread in ratings on all calls for any particular design objective. Design averages cannot shift very far up or down the scale before some listeners become dissatisfied. There is not much of a range in which to operate.

Even in this relatively narrow design range it is wise to set the volumes on the low side of optimum. Experience shows that users will not be satisfied with bad service even at a bargain, so economic considerations lead to an objective somewhere between what is just tolerated and what in itself is preferred, but biased in the preferred direction. This calls for study of Fig. 1, recognizing that the preference tests were made in the absence of cost consideration. The first thing probably noticed is that the peak of the previously mentioned, Fig. 1 was drawn up for trunked calls, assuming a constant loop loss distribution with varying average trunk losses. It could, if necessary, have been made up on an over-all circuit loss basis or could have assumed a constant average trunk loss and a variety of loop loss averages. This was not done because at present about all the loss possible has been squeezed out of loops without getting into big money.

There are many ways to divide the circuit to apportion the loss objectives for trunked calls. Loops and trunks, however, are the natural dividing points, principally because the usage on an individual loop is so much smaller than that on a trunk shared by many users. On an average, a trunk is used about five times as often as a loop. This, coupled with the fact that loops outnumber trunks more than ten to one, makes one willing to spend more money per circuit on trunks than on loops to help transmission on trunked calls. It is simply a matter of getting more for the money.

BROAD OBJECTIVES

This generalized philosophy calls for first doing the things that are economical and that help control loop losses: "For loops, get the best set efficiency, use the high gain sets where needed, use loading where needed, use fine gage to the extent one can signal over it, and then put the burden of loss reduction on the more efficiently used trunks." Before much more can be done to the loop design, further progress is necessary in cutting trunk losses.

Discovering What Needs to Be Done

When objectives have been derived from what the customer himself believes necessary for satisfactory service, the actual job ahead can be measured. The first step undoubtedly is to find out where the telephone system stands with relation to these objectives. This is basic to an evaluation of the size of the transmission correction and quality control job.

Particularly with regard to trunks, there is no substitute to making measurements to see what the actual losses are. Sometimes there is a great deal of difference between what the design calls for and what is actually in place. These checks of actual conditions, especially if made on a sampling basis, are not expensive, but they are certainly necessary for quality control. Of course, the designs themselves need checking to see that they meet modern objectives or are programmed for correction. For loops a check of designs and proper use of the more efficient telephone sets on high-loss loops is also desirable.

Although set surveys and trunk measurements are important, they are only indirect measurements of what the telephone user feels about the quality of service. The closer one gets to the customer in examining the quality of service, the better is the measure of the job being done and of the work that lies ahead.

Three principal schemes are currently being used in the Bell System to measure the product as it is actually delivered. In the first place, a selected sampling of customer opinion is presently being made annually by means of home visits. Known as the "Customer Attitude Survey," it includes questions on the cost of service, quality of service, and opinion of the telephone company. The "quality of service" portion of this survey contains questions on the grade of transmission experienced. The results are published in a booklet entitled "What Customers Think" for information of all departments. By analysis of these periodic surveys, information can be obtained as to the transmission health of the various areas and the locations where further study or surveys need to be made in order to pinpoint the sources of trouble.

The particular questions involving transmission are

If *out-of-town* calls are made, is there anything about the service on these calls that is in any way unsatisfactory?

Possible answer: Yes, or No
(If yes) What is unsatisfactory?.......

When using your telephone at home do you ever have any trouble hearing or being heard?

Possible answers: Very often
Fairly often
Only occasionally
Almost never

In addition to direct customer surveys, two additional means are used to measure quality of service. These are volume measurements on trunk appearances in local central offices, and observations of customer repetition rates and transmission irregularities on intercity calls. Although both of these emphasize physical measurements, they have the advantage of measuring the quality of calls in progress, rather, than indirectly evaluating service by idle trunk measurements. The latter, of course, serve a useful purpose and the direct quality surveys will not supplant them.

The volume survey program was started early in 1957. A high-gain volume indicator is used and a record is made of the volume of the more distant talker. The distributions of volumes measured at each central office are related to the established listener preferences of "Excellent," "Good," or "Poor," adjusted for the loss between the central office and subset. The present goal is to survey volumes in each central office about once a year. Initial results of the volume measurements show about 4% "Poor," 15% "Fair," and the balance "Good" or "Excellent," somewhat short of the current goal. The toll repetition rates are noted on a sample of calls at service observing positions, with a count being made of the number of repetitions per 100 seconds. Note is also made of calls in which customers comment adversely on quality or where, in the observer's opinion, noise, crosstalk, or other impairments are excessive.

The intercity service observations have been particularly useful in comparing performance between different localities and in studying trends. Work is now under way in an attempt to relate the repetition rate performance to volume, and hence to user ratings of "Good," "Fair," etc. It is also proposed to study the advantages of volume measurements on toll connecting trunks to augment the service observations.

Considering trunk design itself, it is recognized that work is needed to bring plant up to the current goal. Present-day trunks are a combination of fairly recent additions and past construction designed for former lower volume objectives. A survey made in 1956 in the Bell System shows that the resultant existing designs, both new and "inherited," range to 12 db or higher. It is reasonable to believe that similar conditions exist in other telephone systems. The average is about 7 db and corresponds to the second dashed line in Fig. 1 marked "Today's Inherited Designs." The ratings for this average loss are in fair agreement with the results of the volume surveys, recognizing the difference between designs and actuality.

Tandem trunk designs in general are still running 2 to 7 db with an average of about 4 db. Since two tandem trunks are required for a tandem call, this results in about the same total trunk loss as the direct path. Note once more that this refers to design and not necessarily to what is actually in service.

From Fig. 1 again, the measure of the job ahead can be seen. Almost 2% of all trunk designs are in the "Poor" category with 11% rated "Fair," and the balance "Good" or "Excellent." Based on current estimates of trunked calls, this means that each day customers would rate about 1.5 million calls "Poor," assuming that performance and design were identical. Fortunately the importance of improved volume is generally being recognized and programs are under way in many locations to bring about progressive improvement.

Conclusions

The work with customer preferences in the field of telephone transmission must form the backbone of design objectives. It demonstrates the inadequacy of cradle-to-the-grave limits in a world of changing preferences.

An appreciation of the background of customer-derived objectives permits establishment of an intelligent and prudent program for up-dating existing plant to modern requirements. It emphasizes the flexibility needed in present designs to care for future changes. With service the main telephone product, its quality control is not a luxury but a business necessity.

Discussion

J. D. Howard, Jr., and J. W. Joyner (Southern Bell Telephone and Telegraph Company, Atlanta, Ga.): This excellent paper describes in simple language the present service goals of the industry and their derivations. If we conscientiously design to these objectives and keep them current and ever before us in the operation of our plant, a good public opinion and its rewards will be ours.

Our current measurement program shows that we are quite a way from the 95% "good," 5% "fair" which we accept as the "happy medium" operating point. In Southern Bell, only 80% of our calls were considered "good" by the customers for 1957. This is probably due as much to a general lack of awareness as to a poor plant inheritance.

Unless the installer who puts in the telephone, the test-deskman who checks the service, the outside plant engineer who designs the loop, and the multitude of others involved in providing telephone service are all aware of the part that their specialty plays in shaping subscriber opinion, the most sincere transmission design is for naught.

Improvement in the quality of telephone service (speed of connection and ease of conversing over the connection) has improved far more than the increase in the cost of that service to our customers and this is as it should be; but if our quality is to continue to improve, we must obtain rates that enable us to program our corrective measures and engineer our new plant to meet our customers' wishes consistent with sound economy.

R. C. Crawshaw (New York Telephone Company, Syracuse, N. Y.): I think Mr. MacAdam's paper spells out a "modern" approach to the transmission job for telephone engineers. It brings the job down to earth. The very end result of many technical endeavors is usually a product to be used by the public at large, whether it is a refrigerator, an automobile, or a telephone system. The engineer, although he must have technical know-how and must deal and think in specialized terms in developing the product, must ultimately have his efforts measured in terms of not what he, the developer, thinks of the technical soundness of the product, but what the user thinks of it as a thing well worth the money. It may be the former (the technical approach) that produces the product but it is the latter (the customer's opinion) that sells it.

Some transmission engineers of the past, and I fear too many, have lived in a kind of ivory tower. They not only set up their own standards to measure the product of their thinking but, what is worse, try always to explain objectives to the uninitiated in technical terms not fully understood by their audience. To use a homely example, this could be like the law breaker setting up his own standards for the measurement of his own innocence (or transgression?). The proposed quality objectives avoid this trap.

This paper performs a very useful task in combining a down-to-earth basis of viewing the effectiveness and real worth of the basic product we sell—transmission—in terms of the customer's opinion of how well it serves his needs and uses. It also defines a better way of explaining it so that transmission engineers can more easily establish their priority for money needs built into construction programs or company budget setups. These remarks are meant to emphasize the need for transmission engineers to make this approach a way of clearly defining the rightful balance between money requirements for "switching" and for "transmission." Otherwise we may find that we have spent millions on far-reaching switching machinery that switches—what?. We may find it all just a technical dream, and perhaps one with which the person paying the bill is not satisfied. Only by measuring the quality of our transmission product both service- and cost-wise from the bill payer's angle can we really know what our mission is and how well we fulfill it. The more our world becomes an engineer's world, the more we need to recognize the need for engineers to be not only more adept technically, but also more adept at interpreting and measuring their field of endeavor in terms of actual human interest and usefullness. This quality control concept of transmission brings our communication system in line with this objective.

Although not mentioned as such in the paper, it is implicitly implied that we must not only place weight on the design and installation of our product, but on the maintenance of it within customer-accepted standards since this too is an essential to quality control. To do this we should know the standards from the customer's view and three ways of measuring our status in this respect are cited. However, I believe there is an interrelation between design and these measured values that does not receive enough attention. It is a need if we are to meet the objectives set up by Mr. MacAdam, and so it is well at least to mention the practical side of keeping our actual performance in line with objectives as we go deeper into automation, with loss of employee contact, and as we work down to lower losses.

First, we must be sure that we design into our plant and equipment proper maintenance margins. I do not mean margins as an allowance for poor maintenance, but with a margin to strike the proper balance between investment and maintenance costs. The more strictly we maintain design tolerances, the more likely it is that the maintenance job will become more technical than the "going" know how of the talent we *can afford* to assign to the everyday job, and perhaps than we can produce by realistic hiring and training procedures. It is a matter of economics. I would suggest some soul-searching on the part of design and circuit layout engineers to be sure we get the right balance between investment and maintenance costs. We should be sure that we are not relying too much on the maintenance side of the ledger in trying to meet our customer objectives.

Second, some further thought might well be applied to the test gear we engineer for the maintenance man. These things too are an important part of the engineer's job in quality control and in meeting the customers' needs economically. One has only to look at a list of the growing amount of test gear applied to all types of transmission channels these days and the cost and effort required to keep them calibrated and working right to realize there may be something to this point in furthering our transmission objectives from the customer's point of view.

I suspect these two points sum up the basic reasons that have tended to bring the transmission maintenance engineer again more prominently into our thinking in recent years.

The measurement of the quality of our product from the customer's angle is a realistic guide in setting technical standards of design and maintenance. Further work along this line is needed as is pointed out in the paper. The control of this quality is in the hands of the design and maintenance engineer as far as providing the gear and the tools for its accomplishment. Our programs need to be continuously scrutinized to be sure we are meeting these standards with the proper balance between investment and maintenance dollars.

W. K. MacAdam: I was much interested in the thoughts and constructive comments of the discussers.

It seems to me that Mr. Howard and Mr. Joyner have put their finger on a tremendously important aspect of providing good telephone service, or for that matter, any other kind of customer service: compensatory rates. Only a company that is in good shape dollar-wise can stay in good shape equipment-wise; and the provision of modern equipment, properly and adequately maintained, is essential to the provision of the quality of service customers prefer. If one needs more evidence in support of this contention he might ask the next suburban commuter he meets in virtually any large city.

Mr. Crawshaw's remarks suggest that a large part of the burden for effective maintenance rests squarely on the shoulders of the engineers designing and planning for new facilities. This is certainly true. In fact, the problem is becoming more acute daily as more and more electronic devices find their way into the telephone plant. We must not only be increasingly diligent but we must learn how to be more ingenious. When engineers recognize that they share the responsibility for good maintenance, however, I am sure that we are off to a good beginning.

An Electric Circuit Theory Approach to Finite Difference Stability

WALTER J. KARPLUS
NONMEMBER AIEE

ONE of the major difficulties involved in the numerical solution of partial differential equations of the parabolic or hyperbolic type by means of finite difference approximations is the tendency of the solution to be unstable under certain conditions. If instability exists, a small error (e.g., round-off error) arising at some point in the computation procedure, tends to become larger and larger as the computation progresses, until the error terms completely overshadow the desired solution, making it worthless. Some finite difference approximations appear to be stable under any condition; others are always unstable; while some are stable only if the spacing intervals satisfy certain requirements.

The two most familiar criteria for testing difference equations for stability are those due to Hildebrand[1] and to von Neumann as described by O'Brien.[2] In both of these methods, it is assumed that the solution of the finite difference equation may be expressed as a product of functions, each depending on only one of the independent variables of the equation. This general solution is then analyzed to determine what requirements must be met by the coefficients of the equation, so that a computational error necessarily decays when one of the independent variables (usually time) goes to infinity.

A different approach to the stability problem follows from the recognition that the voltage or current distribution of a network of electrical resistors arranged in a regular pattern may be expressed compactly by a finite difference equation. Conversely, a finite difference equation may be considered to have an electrical resistance network analog. It follows that any instability in the finite difference network must be reflected as electrical instability in the analogous electric network. Where a small computational error in a numerical finite difference computational procedure gradually tends to grow to infinity, so in the electric network the appearance of a small voltage or current "noise" may be expected to grow indefinitely. This paper represents an effort to apply circuit theory concepts, for dealing with electrical instability, to the problem of determining whether a given finite difference equation, representing an approximation to a partial differential equation, is stable or unstable.

Stability of Resistance Networks

A homogeneous rectangular resistance network may be thought of as being composed of "building blocks" of either of the two basic types shown in Fig. 1, which are repeated in both space directions (*m* and *n*) either to infinity or until a specified boundary is reached. Kirchhoff's current law $\Sigma i_n=0$ relates the potentials V of the adjacent nodes to the potential at node *m*, *n*, in Fig. 1(A):

$$\frac{V_{m-1,n}-V_{m,n}}{R_1}+\frac{V_{m,n+1}-V_{m,n}}{R_2}+\frac{V_{m+1,n}-V_{m,n}}{R_3}+\frac{V_{m,n-1}-V_{m,n}}{R_4}=0 \quad (1)$$

while Kirchhoff's voltage law $\Sigma e_l=0$ expresses the loop current of loop *m,n* in terms of the currents in the adjacent loops:

$$R_1(i_{m,n+1}-i_{m,n})+R_2(i_{m+1,n}-i_{m,n})+R_3(i_{m,n-1}-i_{m,n})+R_4(i_{m-1,n}-i_{m,n})=0 \quad (2)$$

The resistance network is considered stable if a perturbation voltage at node *m,n* in Fig. 1(A) or a current in loop *m,n* of Fig. 1(B), which may be due to noise or other causes, approaches zero and dies out after excitation is removed. Evidently if all resistors have positive values, the network must be stable, since it then contains only dissipative elements and will return to an electrically quiescent state as soon as all the applied energy has been dissipated. It is the presence of active elements in the form of negative resistors which may or may not cause the network to feed back more energy to the node or loop under consideration than was applied originally.

A complete analysis of a large network, containing negative resistors to determine its response to a small transient excitation at some loop or node within the network, can be laborious. A more convenient approach is to recognize the regular repetitive nature of the network and to reason that if a typical building block of the network is stable, i.e., if the building block acts to dissipate rather than supply energy in response to an excitation, then the entire network must be stable. This must be true, since any energy not dissipated by the block to which the excitation is applied will be fed to adjacent blocks which are also dissipative in nature. The problem is reduced therefore to the specification of the conditions under which a typical building block is stable. In the current analog, Fig. 1(A), this implies grounding all nodes except node *m,n* and applying a voltage impulse to this node. If the network is stable, no current will flow through the resistors after the excitation becomes zero. Likewise, in the voltage analog, Fig. 1(B), all loops except loop *m,n* are opened, and a current source is inserted in the loop. If the network is unstable, a current will continue to flow through the loop after the current source is removed.

To determine under what conditions typical network units, as shown in Fig. 1, are stable, it is necessary to consider in detail the operation of negative resistors in electrical circuits. Such a discussion is presented in the Appendix. All positive resistors, comprising the typical node or loop, are lumped together into a single resistor of magnitude R_p, while all negative resistors are combined to form a single negative resistor of magnitude R_n, as shown in Fig. 2. It is then demonstrated that the typical node Fig. 2(A) is stable only if $R_p>R_n$, and that the typical loop, Fig. 2(B), is stable only if $R_p<R_n$.

Application to Finite Difference Equations

The application of the foregoing theory to finite difference equations is best explained by considering, as an example, the wave equation

$$\frac{\partial^2 w}{\partial x^2}=\frac{\partial^2 w}{\partial t^2} \quad (3)$$

and its customary difference form

$$w_{m+1,n}-2w_{m,n}+w_{m-1,n}=k^2(w_{m,n+1}-2w_{m,n}+w_{m,n-1}) \quad (4)$$

where $k\equiv\frac{\Delta x}{\Delta t}$

$$w_{m,n}\equiv w(x,\ t)$$

$$w_{m+1,n+1}\equiv w(x+\Delta x,\ t+\Delta t)$$

Paper 58-60, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2-7, 1958. Manuscript submitted October 10, 1957; made available for printing December 9, 1957.

WALTER J. KARPLUS is with the University of California, Los Angeles, Calif.

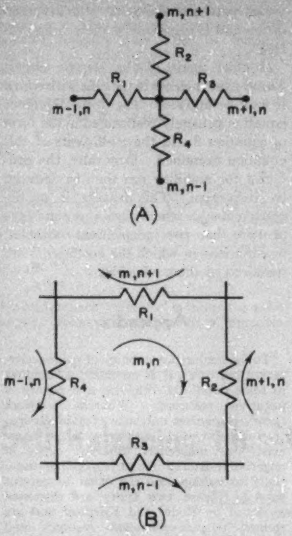

Fig. 1. **Building blocks of resistance network**

A—Node basis B—Loop basis

This expression, when rearranged as

$$(w_{m+1,n}-w_{m,n})+(w_{m-1,n}-w_{m,n})-k^2(w_{m,n+1}-w_{m,n})-k^2(w_{m,n-1}-w_{m,n})=0 \tag{5}$$

is seen to be of the same form as equations 1 and 2. In accordance with the latter of these equations, equation 5 may be identified with a resistance network, whose basic building block is a loop of four resistors: $+1$, $+1$, $-k^2$, and $-k^2$ in magnitude. The stability condition that $R_p<R_n$ then implies that the finite difference equation 4 is stable only if

$$(+1\ +1)<(+k^2+k^2) \tag{6}$$

or

$$k>1 \tag{7}$$

This, incidentally, is precisely the same result as that obtained by applying either Hildebrand's or von Neumann's criterion.

The general application of the circuit theory approach to finite difference stability may be summarized as follows:

1. The finite difference equation is arranged in the form

$$1(w_{m+1,n}-w_{m,n})+a(w_{m-1,n}-w_{m,n})+b(w_{m+2,n}-w_{m,n})\ldots+c(w_{m,n+1}-w_{m,n})+d(w_{m,n-1}-w_{m,n})+e(w_{m,n+2}-w_{m,n})\ldots=0 \tag{8}$$

where the subscript m refers to a bounded space co-ordinate, and the coefficients 1, a, b, c, d, etc., are examined.

2. If all the coefficients are positive, the equation is stable.

3. If some of the coefficients are negative, a sufficient condition for stability is that the algebraic sum of all the coefficients be negative.

If the finite difference equation represents an approximation to a partial differential equation, it is in general possible to arrange it in the form of equation 8.

As a second example consider the familiar 9-point expansion of equation 3:

$$k^2(w_{m,n+1}-2w_{m,n}+w_{m,n-1}) = \begin{cases} a(w_{m+1,n-1}-2w_{m,n-1}+w_{m-1,n-1})+ \\ (1-2a)(w_{m+1,n}-2w_{m,n}+w_{m-1,n})+ \\ a(w_{m+1,n+1}-2w_{m,n+1}+w_{m-1,n+1}) \end{cases} \tag{9}$$

which may be expressed as

$$(w_{m+1,n-1}-w_{m,n})+(w_{m-1,n-1}-w_{m,n})-2(w_{m,n-1}-w_{m,n})+\left(\frac{1-2a}{a}\right)(w_{m+1,n}-w_{m,n})+\left(\frac{1-2a}{a}\right)(w_{m-1,n}-w_{m,n})+(w_{m+1,n+1}-w_{m,n})+(w_{m-1,n+1}-w_{m,n})-2(w_{m,n+1}-w_{m,n})-\frac{k^2}{a}(w_{m,n+1}-w_{m,n})-\frac{k^2}{a}(w_{m,n-1}-w_{m,n})=0 \tag{10}$$

The sum of the coefficients of equation 10 is

$$\left(-\frac{2k^2}{a}+2\left(\frac{1-2a}{a}\right)\right)$$

The sufficient condition for stability, therefore, is that

$$k^2>(1-2a) \tag{11}$$

for $a<1/2$, while the expression is always stable if $a>1/2$. This result is slightly more conservative than the corresponding von Neumann condition

$$k^2>(1-4a)$$

The analysis of equations with more than two independent variables is equally straightforward. Consider the 2-dimensional wave equation

$$\frac{\partial^2 w}{\partial x^2}+\frac{\partial^2 w}{\partial y^2}=\frac{\partial^2 w}{\partial t^2} \tag{12}$$

and its finite difference expansion

$$\frac{w_{m+1,n,\rho}-2w_{m,n,\rho}+w_{m-1,m,n,\rho}}{\Delta x^2}+\frac{w_{m,n+1,\rho}-2w_{m,n,\rho}+w_{m,n-1,\rho}}{\Delta y^2}=\frac{w_{m,n,\rho+1}-2w_{m,n,\rho}+w_{m,n,\rho-1}}{\Delta t^2} \tag{13}$$

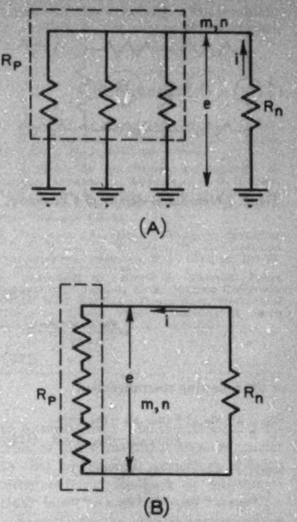

Fig. 2. **Building blocks including negative elements**

which may be expressed as

$$(w_{m+1,n,\rho}-w_{m,n,\rho})+(w_{m-1,n,\rho}-w_{m,n,\rho})+l^2(w_{m,n+1,\rho}-w_{m,n,\rho})+l^2(w_{m,n-1,\rho}-w_{m,n,\rho})-k^2(w_{m,n,\rho+1}-w_{m,n,\rho})-k^2(w_{m,n,\rho-1}-w_{m,n,\rho})=0 \tag{14}$$

where

$$l\equiv\frac{\Delta x}{\Delta y}$$

$$k\equiv\frac{\Delta x}{\Delta t}$$

Summation of the coefficients immediately leads to the condition

$$k^2>(1+l^2) \tag{15}$$

as being sufficient to guarantee stability.

Nor is this approach limited to equations which correspond directly to complete electric networks. With some circumspection it may be extended to equations for which topological considerations permit the construction of an analog of no more than the basic building block. For example, the diffusion equation

$$\frac{\partial^2 w}{\partial x^2}=\frac{\partial w}{\partial t} \tag{16}$$

may be expanded in any of the following ways:

$$\frac{w_{m+1,n}-2w_{m,n}+w_{m-1,n}}{\Delta x^2}=\frac{w_{m,n}-w_{m,n-1}}{\Delta t} \tag{17A}$$

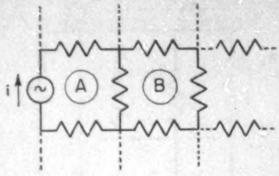

Fig. 3. Network in vicinity of a boundary

$$=\frac{w_{m,n+1}-w_{m,n-1}}{2\Delta t} \tag{17B}$$

$$=\frac{w_{m,n+1}-w_{m,n}}{\Delta t} \tag{17C}$$

or the following rearrangement

$$(w_{m+1,n}-w_{m,n})+(w_{m-1,n}-w_{m,n})+k(w_{m,n-1}-w_{m,n})=0 \tag{18A}$$

$$(w_{m+1,n}-w_{m,n})+(w_{m-1,n}-w_{m,n})-\frac{k}{2}(w_{m,n+1}-w_{m,n})+\frac{k}{2}(w_{m,n-1}-w_{m,n})=0 \tag{18B}$$

$$(w_{m+1,n}-w_{m,n})+(w_{m-1,n}-w_{m,n})-k(w_{m,n+1}-w_{m,n})=0 \tag{18C}$$

where

$$k\equiv\frac{\Delta x^2}{\Delta t}$$

By inspection, equation 18(A) is seen to be always stable, 18(B) always unstable; and 18(C) is stable for $k>2$.

The more complicated parabolic equation

$$\frac{\partial^2 w}{\partial x^2}+\frac{\partial w}{\partial x}=\frac{\partial w}{\partial t} \tag{19}$$

is expanded as

$$\frac{w_{m+1,n}-2w_{m,n}+w_{m-1,n}}{\Delta x^2}+\frac{w_{m+1,n}-w_{m,n}}{\Delta x}=\frac{w_{m,n+1}-w_{m,n}}{\Delta t} \tag{20}$$

$$(w_{m+1,n}-w_{m,n})+(w_{m-1,n}-w_{m,n})+h(w_{m+1,n}-w_{m,n})-k(w_{m,n+1}-w_{m,n})=0$$

where

$$h\equiv\Delta x,\ k\equiv\frac{\Delta x^2}{\Delta t} \tag{21}$$

The simple addition of the coefficients of equation 21 then leads to the stability condition

$$k>2+h \tag{22}$$

identical to that obtained by von Neumann's method.

Effect of Boundary and Initial Conditions

Both von Neumann's and Hildebrand's criteria are conservative for any particular problem because they are applicable for any set of "proper" boundary and initial conditions. For a secific boundary condition the actual stability requirement may be less severe. A similar limitation applies to the method just described. An equipotential boundary of a field described by a difference equation is reflected in the electrical analog, constructed on the voltage law basis, as a constant current boundary, (since loop currents correspond to the potential at the node points of the finite difference grid). That is, every loop adjacent to the boundary must include a constant current source, as shown in Fig. 3. It is evident that loop A in Fig. 3 must be stable regardless of the magnitudes of the positive and negative resistors comprising this loop. This is true because the constant current source forces the current in loop A to have a constant magnitude. This forcing effect is felt, to a somewhat lesser extent, in the adjacent loop B, so that the stability condition of this loop is less severe than would ordinarily be the case. As the distance of the loop under consideration from a specified boundary increases, the stabilizing effect of that boundary decreases. Where one of the independent variables, e.g., time, goes to infinity, this effect eventually becomes negligible and the foregoing analysis applies.

In general, it is to be expected therefore that the stability condition derived from an electric circuit approach will be overconservative unless specific account is taken of the effect of the boundary potentials. Occasionally, where a relatively large net interval is employed, it is possible to construct the entire analog network and deduce the stability condition for each region in the network.

Conclusions

A criterion for the stability of finite difference equations, representing expansions of partial differential equations, has been developed. This criterion is based on the stability analysis of an electric network whose equilibrium equations have the same form as the finite difference equation under study. The results of applying this criterion to a number of difference equations when compared with the results of applying the more familiar stability criteria of Hildebrand and von Nuemann, show that the electrical analog approach frequently yields precisely the same stability condition and is occasionally more conservative.

A chief merit of the electric circuit theory approach lies in the ease with which it may be applied. The finite difference equation is merely rearranged in the form of equation 8 and the coefficients of this equation examined. Generally, the condition for stability can then be deduced by inspection. This feature is particularly valuable when examining equations of more than two independent variables, or equations in which the coefficients are functions of these variables.

Appendix

To determine the stability of nonreactive, active networks, it is necessary to analyze in some detail the behavior and nature of negative resistors. Whereas network theory recognizes only one type of dissipative element, the positive resistor, there exist two inherently different types of negative resistors: one corresponding essentially to voltage and the other to current sources. These two types are discussed in detail by Bode[3] and Karplus[4] and are termed current-controlled resistors and voltage-controlled resistors. In a voltage-controlled negative resistor, the current through the element is a specified function of the applied voltage, as determined by the magnitude of the resistor. However, the voltage drop, which is produced as a result of an applied current, bears no meaningful relationship to the magnitude of this current. In this respect, this type of element is similar to a constant current source. Likewise, in analyzing a current controlled device, it is meaningful to talk only of the voltage response to an applied current. Therefore, before it is possible to determine the behavior of this element in an electrical network, it is necessary to know with which type of negative resistor one is dealing.

This consideration becomes important when Kirchhoff's laws are applied to a network containing negative resistors. Since the basic node and loop equations 1 and 2 make no distinction between the two types of negative resistors, it follows that some assumption is made implicitly in writing these equations. For example, Kirchhoff's current law, when applied to a node formed by three positive resistors and one negative resistor, states that, given the current through the three positive resistors, the current through the negative element is automatically determined. The voltage drop across this resistor then adjusts accordingly. The application of the current law therefore predicates that all negative resistors are of the current-controlled type. Similar considerations indicate that the voltage law is applicable only to negative resistors of the voltage-controlled type.

If one of the resistors in Fig. 1(A) is negative, and if equation 1 is to be applicable, this resistor must be assumed to be of the current-controlled type. The stability analysis of the network block then proceeds as follows: all node points except point m,n are assumed grounded; all positive resistors may then be lumped together and designated by R_p, while the negative resistor is designated by R_n as shown in Fig. 2(A). If now a small voltage e appears at node m,n, a current i is produced through R_p, so that

$$i=\frac{e}{R_p} \tag{23}$$

which must return through the current controlled resistor R_n. This current produces a regenerative feedback voltage e' at node m,n

$$e'=e\left(\frac{R_n}{R_p}\right) \tag{24}$$

If this feedback voltage e' is larger than the applied voltage e, the circuit is unstable and the node voltage will rapidly increase to infinity in response to a finite excitation. Stability is therefore possible only if $R_p > R_n$.

Likewise, if one of the resistors in Fig. 1(B) is negative and equation 2 employed, this resistor must be of the voltage-controlled type. All the positive resistors may then be lumped together as shown in Fig. 2(B) and a small current i may be assumed to arise in the loop, all other loops being assumed open-circuited. This current then produces across R_p a voltage e

$$e=iR_p \tag{25}$$

This voltage also appears across R_n and a feedback current i' flowing in the same direction as i

$$i'=i\left(\frac{R_p}{R_n}\right) \tag{26}$$

results. If i' is larger than i, the loop current will grow to infinity. The condition for stability in this case is therefore that $R_p < R_n$.

Self-Balancing Flux-Gate Magnetometers

WILLIAM A. GEYGER
MEMBER AIEE

Synopsis: This paper is concerned with the application of the self-balancing magnetic-amplifier technique in the realm of flux-gate magnetometers. It describes a second-harmonic type of self-balancing flux-gate magnetometer which is operated in conjunction with a push-pull magnetic amplifier in such a way that the d-c flux in the high-permeability cores of the magnetometer is completely balanced by an opposing d-c flux. Thus, the magnetic field to be investigated, e.g., the earth's field in the vicinity of the magnetometer, remains substantially undisturbed. The compensating d-c flux is linearly proportional to the average value of the polarity-reversible unidirectional output current of the magnetic amplifier. With infinite internal gain ("critical regeneration"), this current is varied by an infinitesimal d-c flux increment in the cores of the magnetometer and may be indicated and/or recorded by means of high-precision moving-coil instruments or d-c potentiometer recorders. In a modified arrangement, the self-balancing flux-gate magnetometer is used as a "gradiometer" for measurement of inhomogeneity of magnetic fields.

THE FLUX-GATE magnetometers[1] are those belonging to the large group of magnetically controlled saturable-reactor devices which are based upon the process of magnetizing a high-permeability core by a periodically varying magnetomotive force, and by a unidirectional magnetomotive force, independently and simultaneously. There is obviously a very close linkage between flux-gate magnetometers and magnetic amplifiers because similar magnetic-core arrangements and similar circuit techniques are used. The essential difference between flux-gate magnetometers and magnetic amplifiers consists merely in the fact that in the first case the saturable-reactor device is controlled by the magnetic field to be measured, whereas in the second case this device is controlled by the electric current or voltage to be amplified. Of course, further differences are concerned with the various forms of magnetic-core arrangements, e.g., permalloy cores of flux-gate magnetometers in the form of a rod (open magnetic circuit), and spirally-wound Orthonol tape cores of magnetic amplifiers (closed magnetic circuit).

With regard to basic principle of operation and circuit techniques, flux-gate magnetometers may be classified as follows:

First are the fundamental-frequency type of magnetometers, in which the impedances of saturable-reactor elements in a-c bridge or differential circuits are varied in accordance with the actual magnitude and direction of the magnetic field to be measured. The fundamental principle of these magnetometers is similar to that of magnetic amplifiers utilizing either external feedback or self-saturation.

Second are the second-harmonic-type magnetometers, in which saturable-transformer elements acting as a magnetic frequency doubler produce a second-harmonic voltage which corresponds with regard to magnitude and phase relationship to a second-harmonic reference voltage to the actual magnitude and direction of the magnetic field to be measured.

G. Barth[2,3] introduced various forms of fundamental-frequency-type flux-gate magnetometers utilizing either external feedback or self-saturation. The aim of his research and development work consisted in applying improved magnetic-amplifier techniques in the field of flux-gate magnetometers in order to achieve high sensitivity and the possibility of multistage design with succeeding magnetic-amplifier stages. These full-wave and half-wave flux-gate magnetometers are very similar to the various forms of external-feedback and self-saturating circuits, as used in the magnetic-amplifier art. They may be operated either in the conventional way from an a-c power supply, or in some modified arrangements from a d-c power supply in connection with a mechanical-switch device acting as a chopper or modulator.

Considerable effort has been expended in the study and development of second-harmonic-type flux-gate magnetometers. In 1928, Aschenbrenner and Goubeau[4] applied such a device for recording the changes in intensity of the earth's field. The second-harmonic-type flux-gate magnetometer is an excellent direction finder

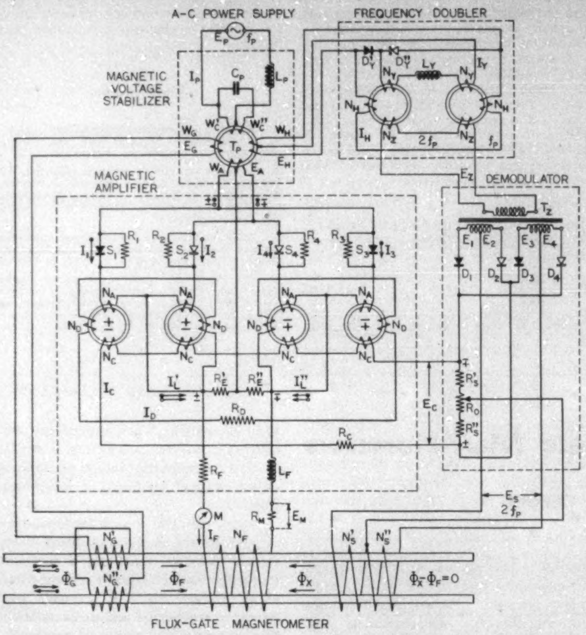

Fig. 1. Circuit diagram of a second-harmonic-type self-balancing flux-gate magnetometer

and may be used as a compass (permalloy compass). This type of flux-gate magnetometer is particularly suitable for geophysical measurements and special military magnetic air-borne detector applications. There are also numerous other possibilities for taking advantage of the very high sensitivity of second-harmonic-type flux-gate magnetometers, e.g., detection of iron particles in aluminum or copper rods, automatic compensation of the earth's field in test rooms, etc. A survey on this subject with references to the literature has been given elsewhere.[1]

This paper is concerned with the possibility of operating a flux-gate magnetometer in such a way that the d-c flux in the high-permeability cores is completely balanced by an opposing d-c flux so that the magnetic field to be investigated, e.g., the earth's field in the vicinity of the magnetometer, remains substantially undisturbed. In a typical example of a 400-cycle-operated self-balancing flux-gate magnetometer, a conventional self-saturating magnetic-amplifier push-pull circuit is d-c controlled from a second-harmonic-type flux-gate magnetometer in such a way that the output current of the magnetic amplifier is varied by an infinitesimal d-c flux increment in the cores of the magnetometer. With infinite internal gain (critical regeneration), the average value of the polarity-reversible unidirectional output current of the magnetic amplifier is linearly proportional to the d-c flux to be measured (the linearity error is of the order of 1/10 of 1%). This output current may be indicated and/or recorded by means of high-precision moving-coil instruments or d-c potentiometer recorders.

In accordance with the specific properties of negative-feedback amplifiers, the accuracy of self-balancing flux-gate magnetometers is substantially independent of changes of the characteristics of circuit components, large variations in magnitude and frequency of the a-c power supply, and load-circuit resistance. Besides these special features, self-balancing flux-gate magnetometers offer the general advantages of magnetic amplifiers and similar devices with transformerlike structures, i.e., elimination of movable parts and vacuum-tube components, sturdiness and reliability, almost unlimited life, etc.

Measurement Principle

Fig. 1 shows the circuit diagram of a second-harmonic-type self-balancing flux-gate magnetometer having two equally rated saturable-transformer elements with high-permeability (e.g., supermalloy) cores, in the form of a rod ("open" magnetic circuit). It is to be noted that the longitudinal dimension of these cores is great in proportion to the transverse dimension. The primary windings N_G', N_G'' of the saturable-transformer elements are supplied from the secondary winding W_G (voltage E_G, frequency f_P) of a power-supply transformer T_P, which also feeds the magnetic amplifier and the frequency doubler, which provides the double-frequency reference voltage E_Z of the demodulator acting as a phase-sensitive rectifier with the operating frequency $2f_P$.

To obtain extreme stability of operation, it may be advisable to employ a magnetic voltage stabilizer (ferroresonant circuit) consisting of a nonlinear reactor T_P with almost rectangular magnetic characteristic, a capacitor C_P, and a linear reactor L_P. In this case, a square-wave voltage E_G (frequency f_P) is applied to the primary windings N_G', N_G'' of the saturable-transformer elements; and square-wave voltages E_A, E_H are applied to the magnetic amplifier and the frequency doubler with demodulator.

The operation of the second-harmonic-type flux-gate magnetometer is based on the differential magnetization of the two saturable-transformer elements by the d-c flux Φ_X to be measured acting in conjunction with the a-c ampere-turns of the series-opposing connected primary windings N_G', N_G'' (a-c flux Φ_G). When $\Phi_X=0$, then the equal and opposite voltages induced in the common center-tapped secondary winding $N_S'N_S''$ are identical in waveshape, and they balance each other in their effect upon the demodulator input circuit ($E_S=0$). However, when a d-c flux Φ_X is applied, the voltages induced in $N_S'N_S''$ become asymmetrical, and a second-harmonic voltage E_S ($2f_P$) appears on the demodulator input circuit. It is to be noted that the phase of E_S (the phase relationship with regard to the second-harmonic reference voltage E_Z) reverses when the direction of Φ_X is reversed.

The graphic symbols of Fig. 1 (black arrow and white arrow indicating the direction of the a-c flux Φ_G in the saturable-transformer elements) show that the d-c flux Φ_X aids the flux component of the first primary winding N_G' and opposes that of the second primary winding N_G'', or vice versa, during the half-cycle periods of supply voltage E_G. As a result, two highly asymmetrical voltage components are induced in the secondary winding $N_S'N_S''$, and a phase-reversible second-harmonic voltage E_S will be applied to the demodulator input circuit. This voltage E_S is, within certain limits, proportional to the actual magnitude of the d-c flux Φ_X. In the arrangement of Fig. 1, a "star-modulator" full-wave type of phase-sensitive rectifier[5] with second-harmonic reference voltage E_Z is employed for converting the phase-reversible second-harmonic voltage E_S across $N_S'N_S''$ into a polarity-reversible d-c signal voltage E_C, which is applied to the control circuit of the magnetic amplifier.

It has been pointed out previously[6] that in a second-harmonic-type flux-gate magnetometer, the d-c flux to be measured may be completely compensated by the opposing d-c flux of a variable direct current, preferably in such a way that the arrangement will be automatically balanced by means of conventional self-balancing instruments, as used in the technique of self-balancing d-c potentiometers. In the arrangement of Fig. 1, the flux-gate magnetometer and a push-pull self-saturating magnetic amplifier with infinite internal gain are operated so that the d-c flux Φ_X to be measured is completely balanced by an opposing d-c flux Φ_F which is linearly proportional to the average value of the polarity-reversible unidirectional output current I_F of the magnetic amplifier. Actually, when employing a properly designed magnetic-amplifier circuit with Orthonol tape cores and silicon junction diodes, the d-c flux $(\Phi_X-\Phi_F)$ is reduced to about 1/1,000 of its original value (Φ_X). Thus, the magnetic field to be investigated, e.g., the earth's field in the vicinity of the magnetometer, remains substantially undisturbed.

The basic principle of the self-balancing flux-gate magnetometer, Fig. 1, consists in supplying a variable polarity-reversible negative-feedback current I_F to compensating winding N_F so that the d-c flux Φ_X to be measured is completely balanced by the opposing d-c flux $\Phi_F=\text{constant}\times I_FN_F$. In this case, $\Phi_X-\Phi_F=0$, and the second-harmonic voltage E_S across secondary winding $N_S'N_S''$ is zero. The relationship between Φ_X and the average value of I_F is linear (the linearity error is of the order of 1/10 of 1%, in accordance with similar performance of self-balancing magnetic amplifiers[7,8]). As indicated in Fig. 1, a choke coil L_F is inserted in series with negative-feedback winding N_F to prevent second-harmonic current from flowing through this winding.

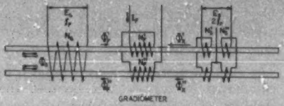

Fig. 2. Arrangement of windings of a self-balancing flux-gate magnetometer for measurement of inhomogeneity of magnetic fields: "gradiometer"

The negative-feedback current, $I_F=\text{constant}\times\Phi_X$, may be indicated and/or recorded by means of high-precision moving-coil instruments or d-c potentiometer recorders. When employing additional magnetic-amplifier stages, the voltage drop $E_M=I_FR_M=\text{constant}\times\Phi_X$ may be applied to the control circuit of a self-balancing magnetic amplifier operating under voltage-balance conditions. Another possibility consists in applying the negative-feedback current I_F to the control windings of a current-type self-balancing magnetic amplifier in a multistage design with succeeding magnetic-amplifier stages.

In accordance with the specific properties of negative-feedback amplifiers, the accuracy of such self-balancing flux-gate magnetometers is substantially independent of changes of the characteristics of circuit components, including the saturable-transformer elements with windings $N_G'N_G''$, N_F, and $N_S'N_S''$. Furthermore, the operation of the flux-gate magnetometer will not be substantially affected by large changes in magnitude and frequency of the a-c power supply (E_P, f_P), and load-circuit resistance (R_F).

In the typical example of Fig. 1, the push-pull self-saturating magnetic amplifier has two equally rated saturable-reactor systems (the plus-minus system and the minus-plus system) with gate windings N_A, d-c control windings N_C, and positive-feedback (boosting) windings N_D providing critical regeneration,[7,8] i.e., infinite internal gain. The resultant voltage drop across series-mixing resistors R_E', R_E'' is proportional to the actual resultant load current $(I_L'-I_L'')$, where $I_L'=I_1+I_2$, and $I_L''=I_3+I_4$. The two saturable-reactor systems are combined in the usual way by means of supply transformer T_P. Quiescent-current values are conveniently adjusted with parallel resistors R_1 to R_4, across silicon junction diodes S_1 to S_4. In accordance with the basic principle of self-balancing magnetic amplifiers, the regeneration-control resistor R_D will be adjusted so that the control-winding current $I_C=E_C/R_C$ is substantially reduced to zero. Proper adjustment of R_D may be achieved easily by means of a microammeter consisting of a lightspot galvanometer with low-resistance shunt (I_C is of the order of ±1 to 2 microamperes): If R_D is adjusted below or above the point of critical regeneration while the cores of the flux-gate magnetometer are subjected to variations of d-c flux Φ_X, a control-winding current I_C will appear but it will be of a direction of current flow dependent upon the direction of actual misadjustment. With critical regeneration, $E_C=0$, $E_S=0$, and $\Phi_X-\Phi_F=0$. In this case, the negative-feedback current I_F indicated by the ammeter M provides full-balance condition[6] of the flux-gate magnetometer: $I_F=\text{constant}\times\Phi_X$.

The star-modulator full-wave type of phase-sensitive rectifier[6] (demodulator) contains the reference-voltage transformer T_Z with two center-tapped secondary windings (voltages E_1 to E_4), four silicon junction diodes D_1 to D_4, a pair of mixing resistors R_S', R_S'', and a potentiometer resistor R_0 for zero adjustment ($E_C=0$ with $E_S=0$). The primary winding of T_Z is supplied from a conventional type of magnetic frequency doubler consisting of two equally rated saturable-transformer elements with Orthonol tape cores, series-opposing-connected a-c windings N_H, series-aiding-connected d-c windings N_Y, and series-aiding-connected secondary windings N_Z, which provide the second-harmonic reference voltage E_Z of the demodulator circuit. The direct current I_Y of the frequency doubler is derived by full-wave rectifiers D_Y', D_Y'' from power-supply transformer T_P; and a choke coil L_Y is used so that the second-harmonic current will flow only through the primary winding of T_Z and will not be short-circuited by the components of the d-c circuit (I_Y).

Modifications

In accordance with common practice, the second-harmonic-type flux-gate magnetometer may be applied with modified arrangement of its windings in such a way that the second-harmonic voltage of the secondary winding is linearly proportional to the actual difference between the d-c flux values of the two high-permeability core elements. This differential-type flux-gate magnetometer, sometimes termed "gradiometer," measures the actual difference between the flux in the first core element and that in the second core element. In this modified form, a self-balancing flux-gate magnetometer may be employed for measurement of inhomogeneity of magnetic fields.

Fig. 2 illustrates the possibility of applying the arrangement of Fig. 1 as a gradiometer, merely by modifying the connections of the winding units of the high-permeability core elements. The flux difference $\Phi_X'-\Phi_X''$ to be measured is compensated by the negative-feedback current I_F flowing through the series-opposing-connected compensating-winding units N_F' and N_F''.

In the example of Fig. 2, it has been assumed that the flux Φ_X' in the first core element with winding N_F' is larger (9 units) than the flux Φ_X'' in the second core element with winding N_F'' (3 units), as illustrated by the different lengths of the arrows representing Φ_X' and Φ_X''. Since N_F' and N_F'' are wound in opposite directions, the negative-feedback current I_F will subtract a compensating flux Φ_F' (-3 units) in the first core element and will add an equal amount of compensating flux Φ_F'' ($+3$ units) in the second core element. Thus, in this example, with full-balance conditions, the first resultant flux $\Phi_X'-\Phi_F'=9-3=6$ units will be equal to the second resultant flux $\Phi_X''-\Phi_F''=3+3=6$ units, and the second-harmonic voltages across the secondary winding units N_S', N_S'' will be zero. Therefore, with critical regeneration of the magnetic amplifier, the negative-feedback current I_F is linearly proportional to the actual flux difference $(\Phi_X'-\Phi_X'')$. If the external field to be investigated is homogeneous $(\Phi_X'=\Phi_X'')$, then the negative-feedback current $I_F=0$. However, when there is a certain amount of inhomogeneity $(\Phi_X' \gtrless \Phi_X'')$, then $I_F=\text{constant}\times(\Phi_X'-\Phi_X'')$.

Other possible modifications are concerned with the design of flux-gate magnetometer cores (e.g., with closed magnetic circuit), magnetic amplifier, frequency doubler, and demodulator. Obviously, many other forms of these devices may be used equally well. A permanent-magnet-type frequency doubler[9] has been used successfully, and other forms of phase-sensitive rectifiers[5] may be applied in such arrangements. The magnetic voltage stabilizer may be eliminated in many cases because the stability of operation is inherently very good as a result of the large amount of negative feedback. It is, of course, also possible to supply self-balancing flux-gate magnetometers from a magnetic frequency multiplier or from a switching transistor d-c to a-c converter[10] to reduce the size of the saturable-transformer and saturable-reactor elements, and to increase the speed of response. Finally, it is to be noted that the basic principle of self-balancing flux-gate magnetometers may be applied equally well to those fundamental-frequency-type flux-gate magnetometer circuits[1–8] which are very similar to the various forms of external-feedback and self-saturating circuits, as used in the magnetic-amplifier art.

Conclusions

1. The combination of a second-harmonic-type flux-gate magnetometer and a push-pull magnetic amplifier with infinite internal gain makes it possible to balance the d-c flux in the high-permeability cores of the magnetometer by an opposing d-c flux which is linearly proportional to the average value of the polarity-reversible unidirectional output current of the amplifier. In this case, with critical regeneration, the self-balancing flux-gate magnetometer is operated in such a way that the duodirectional output current of the magnetic amplifier is varied by an infinitesimal d-c flux increment in the core elements of the magnetometer.

2. When employing a properly designed magnetic-amplifier push-pull circuit with Orthonol tape cores and silicon junction diodes, the d-c flux in the cores of the flux-gate magnetometer is reduced to about 1/1,000 of its original value. Thus, the magnetic field to be investigated, e.g., the earth's field in the vicinity of the magnetometer, remains substantially undisturbed.

3. The relationship between the d-c field to be measured and the average value of the polarity-reversible unidirectional output current of the magnetic amplifier is linear (the linearity error is of the order of 1/10 of 1%, in accordance with similar performance of self-balancing magnetic amplifiers). This output current may be indicated and/or recorded by high-precision moving-coil instruments or d-c potentiometer recorders.

4. In accordance with the specific properties of negative-feedback amplifiers, the accuracy of measurements with self-balancing flux-gate magnetometers is substantially independent of changes of the characteristics of circuit components including the saturable-transformer elements of the flux gate. Furthermore, the operation will be substantially unaffected by large changes in magnitude and frequency of the a-c power supply, and by load circuit resistance.

5. Besides these special features, self-balancing flux-gate magnetometers offer the general advantages of magnetic amplifiers and similar devices with transformer-like structures, i.e., the elimination of movable parts and vacuum-tube components, sturdiness and reliability, almost unlimited life, etc.

An Improved 6-Channel Time Division Multiplex for Submarine Cable Telegraphy

H. F. WILDER
MEMBER AIEE

THE DEVELOPMENTS of recent decades have sustained the prediction made in 1890 by Mahan that if a successful transisthmian canal were to be built in Central America, the Caribbean would become a great commercial area and a crossroads of transportation, not only of local and of South American traffic but between Europe and Asia as well.[1] The importance of Havana, Cuba, in the day of the sailing ship, seated as it is in a geographical position so favored by winds and ocean currents as to command the only passage to Europe, has not been diminished but enhanced by the prophesized burgeoning trade and intercourse. To meet the communications needs of this market place and the richly cultivated area to which it gives access, the Western Union Telegraph Company operates three submarine telegraph cables between Havana and Key West, Fla., an average distance of 101 nautical miles. The second cable of the three was laid in 1889, almost as if in anticipation of Mahan's observation, and the third was laid in 1917, three years after the completion of the Panama Canal and, seemingly, in confirmation of it. Until recently, these duplex-operated cables were terminated in differentially connected polar relays reflecting the land-line practice of those decades, a condition sustaining 3-channel multiplex operation or a signalling capacity three times that of the earlier Morse circuits.

Lines to Cuba

Probably no other division of the submarine cable network of the company presents as many diversified traffic requirements as these connections to Cuba and their extensions to South America and the islands of the Caribbean. One requirement, automatic exchange of traffic with the recorder code-operated cable of Cable and Wireless, Ltd., to San Juan, Puerto Rico, was effected by translating the 3-position signals, dot, dash, or space, to 2-element signals of twice the line frequency, and superposing the latter on appropriate segments of one of the New York 3-channel multiplexes. Now, a second interconnection of this nature is in operation. This circuit, the Island Chain, finally terminates in Barbados, B.W.I.

Another early requirement supplied by the company was the transmission to brokerage houses in Havana of the quotations of the New York Stock Exchange. This service was extended from the mainland in 1930 by superposing on one of the three physical circuits a unidirectional single-channel amplitude-modulated carrier system.

Here then, was further indication of the tide of specialized traffic demands arising from the operations of mercantile houses and the international airlines; the mercantile houses trading in sugar (the staple product of the island), coffee, tobacco, fruit, and chocolate. To provide these leased facilities a second carrier system was designed and put into operation in 1949.[2] Each of the two additional frequency-modulated duplex channels so derived is capable of carrying either a teleprinter circuit or a triple-channel multiplex. And in 1950, the older multiplexes were replaced by similar equipment which was capable, however, of accepting and delivering teleprinter start-stop code signals from and to the customer extensions.

Signal-Shaping Amplifiers

The somewhat higher signalling speed of the new multiplexes highlighted the need for a cable receiving device of greater sensitivity and stability than the unaided polar differential relay. Consequently, in 1955 all the Havana cables, together with the Tricore cable between Key West and Miami Beach, were equipped with signal-shaping vacuum-tube amplifiers.

These amplifiers are in widespread use throughout the submarine cable network of the company, to equalize the transmission distortion and to amplify the signals on cables from 50 to 500 miles in length. The output relays are driven by a vacuum-tube amplifier and while earth current potentials and corresponding low-frequency components in the residual duplex unbalance are prohibited from influencing the output because of the discrimination inherent in the equalizing networks, low-frequency signal components equivalent to the suppressed disturbing currents are restored to the signal by a self-energized correction circuit.

High-Speed Signalling

At the time the amplifiers were installed, tests were made to determine the feasibility of higher signalling speeds, for again the pressure for additional channels to Havana was being felt and it was thought that the new amplifiers might be the key to a full exploitation of the latent signalling spectrum of these low-attenuation cables. For the investigation of higher speeds, magnetic tapes were prepared in the laboratory. These contained the signal combinations that would produce the same transmission distortion and attenuation to be encountered at the speed of signalling of a 6-channel multiplex, at 100 cycles per second, compared to the usual 50 cycles, and these tapes were then inserted in a magnetic tape-recorded signal transmitter at Key West for observation at Havana.[3] A signal of good quality was obtained at the higher speed by readjustment of the signal-shaping network in the terminal amplifier, and the duplex balance was easily improved to a workable accuracy. Despite the greater amplification, disturbance from natural sources and transmission on other cables was still negligible, and when the frequency-modulated carrier was superposed on the test cable without mutual interference, practical operation of a 6-channel duplex multiplex circuit on any of the three cables seemed assured.

The success attending these tests represented a real breakthrough in the previous restriction on channels to Havana. The higher signal capacity of 6-channel multiplexes and their compatibility with

Paper 58-44, recommended by the AIEE Telegraph Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted October 11, 1957; made available for printing December 3, 1957.

H. F. Wilder is with the Western Union Telegraph Company, New York, N. Y.

The author wishes to recognize the contributions of the several engineers whose special efforts made the 6-channel idea realizable. S. A. Kirkowski designed the new start-stop distributors, and W. J. Ramhorst, as a continuation of previous submarine cable equipment design, furnished the physical layouts of the racks. Synthesis of the basic circuitry and the carrying of the project to an operative conclusion was done by G. T. Fontaine.

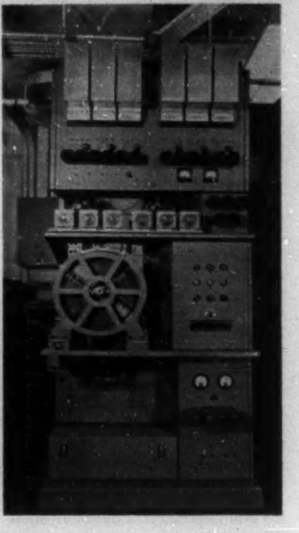

Fig. 1. The sending 6-channel multiplex terminal

the frequency-modulated carrier meant that the number of multiplex channels could be doubled simply by the provision of new terminal equipment, a step comparable to the doubling of transatlantic facilities that had been effected by the insertion of submerged repeaters.

Multiplex Design

Design of the 6-channel multiplex terminals to use the wider signal spectrum now known to be available was soon initiated. Aside from designing for operational stability and the use of well-tried features familiar to the operating personnel, several fundamental decisions were made. In view of the large number of channels ultimately possible, it was thought desirable to avoid use of tape reperforation to couple incoming teleprinter signals to the cable time-division channels. The untidy tape loops and the maintenance of tape continuity were eliminated by the incorporation of a channel repeater between each teleprinter signal-receiving start-stop distributor. Correlated with the decision to use channel repeaters was the limitation of the teleprinter extensions to a speed of 368 operations per minute, nominally referred to as 60-word operation. To have designed for 65 words or 390 operations per minute would have meant the transmission into the domestic telegraph system of teleprinter signals containing rest or stop pulses only 86% of unit length, and this would have precluded regeneration at repeater points, thus rendering the longer teleprinter signal extensions much more susceptible to distortion and bias.

The Sending Terminal

The sending terminal is shown in Fig. 1 and the flow of intelligence through this equipment may be seen in Fig. 2. Each sending rack provides means for coupling six incoming teleprinter lines to their respective 5-unit code multiplex channels. The individual relay banks housing the channel repeaters are mounted at the top of the rack with the teleprinter circuit line and selector relays beneath them. A new start-stop distributor was designed to receive the incoming teleprinter signals from each extension and to deliver the five intelligence impulses to one of two capacitor-storing banks in the associated channel repeater.

A group of three units is driven by a common motor geared to produce the correct brush speed, the engagement of the brush shaft being effected by a dry metallic clutch of recent design significantly free of variation in take-up lag. The brushes are shown at rest on the stop segments of the faceplate; see Fig. 3. Upon the reception of a teleprinter character the clutch magnet circuit is energized by the start impulse of spacing polarity preceding the five intelligence impulses. The brush then rotates for a single revolution, returning to the rest segment coincident with the arrival of the stop impulse of marking polarity at the end of the character. Here it remains until the start impulse of the next character occurs. During its revolution the brush passes over five short-length scanning or pickup segments at intervals of 22 milliseconds. The successive impulse polarities of the five intelligence impulses thus selected are momentarily stored on a relay. The longer segment following each selection is used to deliver a charge from the armature of the relay to an associated capacitor in one or the other of the two capacitor-storing banks in the channel repeater. The stored charges are subsequently commutated by segments on the multiplex faceplate to the coils of five storing relays. After positioning, the armatures of these relays are given time to settle firmly on their contacts before delivery of the signals to the sending amplifier.

To obtain the sixth pulse segment for operation of the transfer relay in the

channel repeater, it was necessary to shorten the fifth delivery segment. Closure of the sixth pulse segment shifts the delivery of the next character received to the alternate bank. Both the sixth and stop segments are isolated by short segments. By means of an indicator knob, the faceplate may be shifted to measure the quality of the incoming teleprinter signal and to center the selection point midway between the minimum limits of variation in signal impulse arrival time.

The large multiplex distributor shown directly below the shelf of six start-stop distributors is already in widespread use as a time division commutator on the North Atlantic system. For use on the Key West to Havana cables, the distributor was equipped with a faceplate possessing on one commutator all the segmented rings necessary to both sending and receiving functions, an interchangeability that reduced the number of units to be manufactured and held in reserve at each station. One ring is segmented to provide 22-millisecond timing intervals for each one of the six channels while either translating the multiplex signals to teleprinter signals at a receiving terminal, or monitoring the signal transmitted to the apex of the cable duplex bridge at the sending terminal. The other rings are segmented in the conventional manner for selection, correcting, transmission of unit length impulses, and local functions.

Channel Repeating

The distributor brushes must rotate slightly faster than the maximum rate of transmission of the incoming teleprinter signals so that, regardless of the normally encountered power frequency changes in the supply to teleprinter keyboard and transmitter-distributor motors, the distributor will never fall behind in phase, but will from time to time "catch up" with the signal input. To stabilize the speed at 375 rpm or at 7 rpm above the maximum teleprinter character rate, the usual sliding weights were removed from the distributor driving fork and the fork inclosed in a draft and sunlightproof cabinet located on the plinth of the rack. With this slight speed differential, the signal attenuation is not appreciably increased and the rest or stop pulse duration of each translated teleprinter character issuing from the receiving rack is still well in excess of unit length. At 375 rpm the length of this pulse is 28 milliseconds or 27% greater than a unit-length impulse of 22 milliseconds. It might be said that the code retransmitted is one of 7.27 units instead of the 7.41-unit code signals originally incoming to the sending rack. Regeneration of the 7.27-unit code signal characters may be effected at one or more repeater points without "clipping" the rest pulse.

About every 8 or 9 seconds, the slight amount of excess multiplex speed causes the brush-extracting intelligence stored in one bank of capacitors to approach the segments associated with the alternative bank. Before a scramble can occur, however, an auxiliary or auto-stop circuit continuously searching for this condition, stops the alternation of the transfer relay feeding information to the multiplex for a single character and substitutes a blank for transmission. Thus a new lag, equivalent to the time duration of a character, is introduced and the cycle repeats. If the power frequency at the sending extension increases, the rate of blank insertion decreases; it increases if the frequency drops below 60 cycles per second. Should the teleprinter extension send sporadically as from a keyboard, more than one blank may be transmitted between characters and in the limit where sending ceases the blank is transmitted continuously.

Way-Station Selection

Leased circuits frequently contain one or more drops or way stations in addition to the terminals and are then provided with way-station selecting apparatus enabling one station to call any other. Station selections are preceded by an open-line condition lasting a few seconds, a signal serving to start all teleprinter motors in anticipation of the transmission of the selection character group itself. Ordinarily, a continuous spacing signal would be sent over a channel of a 5-unit code multiplex as a series of "blanks" equivalent to the idling condition, and the significance of the preselection open-line interval would be lost. The fact that the upper-case shift function or "letters" character is sent but once in traffic operations presented an opportunity to translate the open line interval to a form acceptable to the multiplex. Accordingly, whenever a multiplex channel is assigned to the support of a leased circuit operative with way-station selection, the usual open-line alarm circuit is arranged

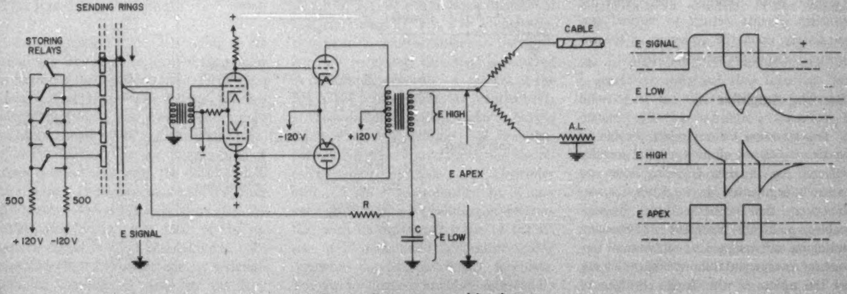

Fig. 4. Transmitting amplifier theory

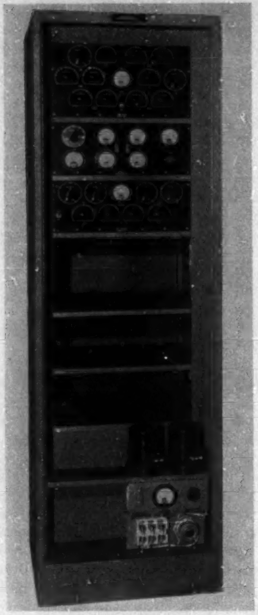

Fig. 5. The receiving signal-shaping amplifier

to send a succession of LTRS (letters) functions (all five impulses of marking polarity) for the 3- to 5-second preselection interval.

At the receiving terminal, the reception of a succession of shift functions, quite in excess of traffic need, is recognized as the preselection open, and in response the terminal apparatus opens the out-going customer extension to activate all teleprinter motors for the call soon to be received. Both sending and receiving sensing circuits return to normal immediately upon the reclosing of the incoming teleprinter circuit extension.[4]

Sending Amplifier

Transmission to a submarine cable at speeds in excess of 50 cycles is usually effected by brushes traveling over accurately segmented rings. It was known, however, that on the three Havana cables, a highly inductive multisection antinoise set designed to suppress all frequency components above 300 cycles lay in the apices of the duplex bridges to prevent physical transmission from interfering with operation of the carrier systems. Since previous experience had demonstrated the impossibility of transmitting from segments to an inductive sending end impedance because of segment gap flashover, it was decided to transmit to the duplex apex from a vacuum-tube power amplifier, which is mounted at the base of the rack to the right of the switch compartment and the sending fork box. To obtain a satisfactory signal shape with the relatively simple networks available in the distant receiving terminal amplifier, however, all frequency components, including the d-c component, must be transmitted to the cable by the sending apparatus. Accordingly, the amplifier was designed to impress only the higher frequency components of the signal upon the duplex apex; the d-c component and the very-low-frequency components are still supplied from the sending segments through a resistive-capacitive network.

Fig. 4 shows the circuit theory of the sending amplifier. Segments of the transmitting ring are protected by unusually large battery tap resistors of 500 ohms so that "bridging" by a worn brush is of no importance. The resistor R of about 1,000 ohms in the LOW path limits the d-c cable current to 40 or 50 milliamperes and the 40-microfarad capacitor C suppresses all high-frequency components while simultaneously providing a low-impedance path to ground for the high-frequency components generated by the vacuum-tube amplifier in the HIGH path. The latter is a push-pull power amplifier transformer coupled to the cable duplex bridge and is driven by a flip-flop vacuum-tube relay that "square up" the otherwise

delay distortion have been eliminated. The entire system is energized from the station 240-volt d-c power and no special cable rectifiers or batteries are required.

Sending Monitor

Experience has shown that it is imperative that the technician be provided with means to monitor the transmitted signals and that the only reliable method is to drive the monitoring device by the current actually entering the apex of the duplex bridge, for then an interruption of the cable or artificial line currents will announce failure in circuit continuity. At the sending terminal, a 5-ohm resistor is placed in series with the output of the sending amplifier and the voltage drop produced across this resistor by the charging currents to the cable apex after amplification drives a high-speed monitor relay. The multichannel multiplex signal output of the relay is then returned to a vacuum-tube translator which, in conjunction with the teleprinter timing ring on the distributor faceplate, restores the start and stop pulses of a given teleprinter channel to permit the technician to observe the transmission of any one multiplex channel on a 60-word teleprinter. The monitor cabinet and channel selector switch are contained in a cabinet adjacent to the multiplex distributor.

At the request of the distant station received either over the international talk-channel or on the Morse facilities provided on these racks, the sending terminal technician can transmit the "all-idle channel" pattern for phasing of the receiving distributor, or a recurrent pattern which is devoid of characteristic distortion, thus enabling the receiving station technician to range and center the signal pickup without requiring the transmission of a test tape.

The Receiving Terminal

In propagation from the sending to the receiving terminal, the form of the signals is degraded by the effects of frequency and delay distortion. On cables of this electrical length, the former effect may reduced the amplitude of the highest frequency reversals to one twenty-fifth of their original size while the delay distortion retards the time of arrival of the lower frequency components relative to the attenuated highs. The form of the received signal is quite unintelligible. To equalize these distortion effects, a signal-shaping amplifier is used on the Key West–Havana cable and on other cables of the same order of attenuation. Two such amplifiers are usually mounted in a single cabinet although but one is shown in Fig. 5. For speeds of operation of over 50 cycles, high-speed relays whose upper limit of operation is several hundred cycles per second are substituted for those shown in the figure.

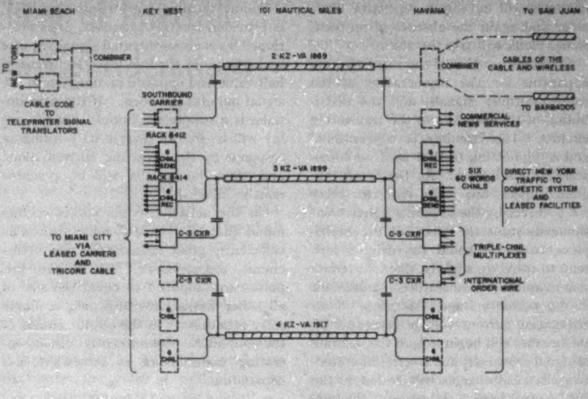

Fig. 8. Ultimate facilities

Adjustable filter sections located in the upper compartment shape the received signals and suppress the very-low-frequency earth current and residual unbalance potentials, and the electrical noise frequencies lying outside the upper end of the signal spectrum. The shaped signal waveform, minus the zero-frequency component, is then amplified by a 2-stage transformer-coupled amplifier driving one or two output relays. The output relay drives the receiving relay loop into the multiplex set and a low-pass filter or local correction network, which restores the d-c signal component.

The 6-channel receiving terminal is shown in Fig. 6, and a block diagram of this equipment in Fig. 7. A single receiving rack complementary to the sending rack previously described is required at each cable terminal. A cabinet at the top of the rack contains six identical sets of vacuum-tube circuitry, each set having three distinct functions. Of first importance is the circuit translating the received multiplex signals to the teleprinter form. This is accomplished by a new vacuum-tube circuit operating in conjunction with its associated group of the six sets of 22-millisecond teleprinter timing segments on the distributor faceplate. The five intelligence impulses received by the multiplex are a little over 5 milliseconds in duration. These are first stored on five capacitors. Each capacitor is then discharged by its respective segment on the teleprinter timing ring through one winding of a transformer having seven primary windings. Of the seven timing segments for each channel, the first segment discharges a positively charged capacitor through the no. 1 winding of the transformer to prefix the start impulse to the teleprinter character being developed. Similarly, a seventh but negatively charged capacitor is provided to produce the stop impulse.

The voltage transients induced in the transformer secondary drive a vacuum-tube bistable amplifier, which in turn positions a relay controlling the outgoing teleprinter line. Auxiliary circuitry holds the line closed whenever traffic ceases.

The way-station selection repeater has been previously described. When not in use, it is switched to sense an open teleprinter line and to bring such an abnormal condition to the attention of the technician.

A channel-failure alarm is the third feature provided. This circuit senses, for a greater-than-normal time interval, the absence of the time differential blanks, caused perhaps by a failure in the channel repeater circuitry or by loss in phase of the receiving distributor. The basis of the circuit is a capacitor charged through a high resistance. If during traffic transmission the time differential blanks do not appear at the usual rate of seven or so per minute the voltage on the capacitor rises excessively and triggers an alarm. Should the distributor drop behind in phase by one or more segments, all idle channels will develop a repetitive character and again the absence of an occasional blank will trip the alarm.

The lower portion of the rack supports apparatus for the regeneration of the cable multiplex signals, and the distribution of the impulses to the translating circuits. The circuitry is conventional and a duplication of that used on transatlantic multiplexes. As the block diagram implies, one relay, corrector relay CRY, driven by the incoming signals, continuously scans the phase of the multiplex brushes. Should the driving fork tend to speed up slightly, due to a reduction in ambient temperature or a decrease in d-c power voltage, the phase of an alternating current voltage generated by the brushes will begin to lead the instants of signal crossover, and a series of corrective electrical charges will be fed to the fork control bank. As a result, the current flowing in a damping coil at the extremities of the fork tines will be decreased thereby lessening the stiffness of the fork and causing it to slow the speed of brush rotation. Conversely the magnetic flux is increased by the same corrective circuits should the fork slow down. Thus, the receiving brushes rotate continuously at precisely the same speed as the sending brushes and in channel phase with them, although because of the time of propagation over the cable, there will be an angular lag equivalent to a fraction of a revolution.

A line relay LRY and a selector relay SRY, operating in conjunction with 30 scanning segments on the faceplate, regenerate the signal impulses and deliver them to 3 storing relays. Storage of the regenerated impulses for a short time permits the scanning segments to be mounted on an orientable ring, enabling the technician to center the range.

On the long transatlantic cables where the amplitude of the most rapid signal reversals is greatly attenuated, the signal-shaping networks of the receiving amplifier are tuned to emphasize the next lowest reversal frequency whose impulses contain two transmitted impulses rather than one. These "doubles" reversals are very much larger than the "singles" and are not degraded by electrical noise. Although under conditions of suppressed singles operation any singly transmitted impulse does not appear in the amplifier output the missing impulse may be interpolated by the use of appropriate circuitry within the multiplex equipment. On the 6-channel terminal a reversing relay RRY is provided for this purpose. It is positioned by each regenerated signal impulse and returns to the line relay a current of half value and opposite in direction to the signal impulse last seen. If the next impulse is a suppressed impulse the line relay will be free to reverse its position in response to the reversing current alone and thus the impulse will be synchronously "filled in."[3]

On the actual Havana cables it was found that the signal-to-noise ratio was sufficiently great to make the use of this circuit unnecessary. The singles impulses are amplified to equal the size of all other frequencies and only a single relay is necessary in the output circuit of the amplifier. Consequently circuit-operating maintenance is somewhat less demanding.

Regulating

When preparing a multiplex facility for traffic use, the attendance of both the sending and receiving terminal technicians is required. First, the sending terminal must be made aware of the need by the receiving terminal for the transmission of the "all channel idle" or "spacing" condition in order that the receiving brushes may be wheeled around until, by observation of the neon phasing lamp bank, channel phase is established. Second, the pattern combination, and a range excursion not less than 50% of the theoretical maximum obtained under duplex conditions must be requested before traffic is accepted. It is necessary therefore that the receiver be able to call in the sending technician, and so each receiving rack is equipped with a loss-of-signal detector. When the need arises, the receiving station simply stops transmission in the opposite direction, thereby immediately alerting the distant sending technican.

Successful Operation

The 6-channel equipment was placed in service early in April 1957. Its immediately successful operation not only provided three additional duplex teleprinter channels to Havana but permitted the 3-channel multiplex then in the old Miami office to be abandoned just prior to the establishment in the new office of more up-to-date operations through Atlanta. A duplicate set of 6-channel equipment is now under construction and other plans are afoot to increase the channels potentially available from the three cables. In Fig. 8, the author indulging in a certain amount of latitude, has sketched the application of the new 6-channel equipments, and the projected carrier channel terminals and recorder code combining apparatus to this communication network. As the need arises, the ultimate realization of a total of some 27-odd duplex and commercial news circuits to Cuba is thus seen in the offing.

A second frequency-modulated carrier shown superposed on cable 4 will be a duplicate of the original; the performance of the latter could scarcely be improved upon, while the replacement of the "old work-horse," the amplitude-modulated carrier, by a 3-channel unidirectional carrier transmitting commerical news service will relieve the existing triple multiplex of the inefficient use of their otherwise duplex operative channels. Similarly, the completion of the design and the installation of special time division apparatus, to combine over a single physical or carrier channel the two duplex recorder code circuits interconnecting with the Cable and Wireless, Ltd., system in the West Indies, will further increase the efficiency of use of the existing 3-channel multiplexes to New York. The bidirectional recorder code to teleprinter signal translators associated with this mode of cable code operation are in the process of development. This apparatus will not only translate the alphanumerical characters of one code to the electrical impulses of another code but will substitute for the special designations which are almost traditional in recorder code the equivalent function characters common to reperforation switching systems. And southbound, other special apparatus adjunct to the translators will automatically inject the correct "attack" or way-station call of the many stations along the island chains.

Nation-wide Switching of Intertoll Trunks—Transmission Considerations

O. F. WALLMAN
MEMBER AIEE

THE successful planning, installation, and operation of a nation-wide switching plan to interconnect more than 62 million telephones in the United States requires a high degree of teamwork between various groups of people. This involves the development, design, transmission, equipment, and building engineers to provide the system and the operating and maintenance people to keep it going. This paper deals primarily with transmission phases of switching telephone trunks in the United States. Brief mention is made of the interconnection with the Canadian switching plan involving approximately 5 million additional telephones.

A 1953 AIEE paper covered the fundamentals underlying the design of intertoll trunks.[1] This paper makes use of the basic data but covers primarily transmission considerations involved in switching of intertoll trunks in the nation-wide switching plan.

A new nation-wide switching plan employing switching machines instead of manual interconnection of intertoll trunks by operators was introduced in the Bell System in 1950.[1-5] The original plan was based on the use of 4-wire switching at all major switching offices and 2-wire switching at toll centers, the junction points between intertoll and exchange facilities.

Since its introduction a number of changes in concept have already been introduced into the plan as follows:

1. Discontinuance of the national center.
2. Introduction of 2-wire switching systems at many of the smaller switching offices.
3. Integration of the switching plans of the United States and Canada in a continent-wide switching plan.
4. New techniques in the assignment and operation of echo suppressors to meet the needs of the expanded switching plan.

A measure of the magnitude and complexity of the transmission problems involved can best be seen from the number of switching points involved. The present view indicates an ultimate total of about 300 major switching offices and about 2,000 toll centers. The plan must be flexible enough to permit interconnection of the facilities in the United States with the European systems through the newly installed transatlantic submarine telephone cable and with the Hawaiian Telephone System through the transpacific submarine telephone cable.

The basic plan for switching together the necessary number of intertoll trunks to permit the interconnection of any two telephone customers in the United States is shown in Fig. 1. It will be noted that the maximum number of trunk circuits in any one connection is nine for a telephone call within the United States. As outlined later, some calls between Canada and the United States may contain a total of ten links. Two of these links, one at each end, connect the customer's telephone from his local central office to the toll network at the toll center. Two such links are in every connection except for those relatively small number of cases where direct intertoll trunks are provided between two local offices in different cities. Their design with relation to return losses in the frequency ranges important from an echo and singing standpoint is covered in another paper.[6] It will be noted in Fig. 1 that the switching offices are given both names and numbers to indicate their rank or class in the switching plan. Some people prefer the names while others prefer numbers in referring to the various trunk links. Each switching office below the rank of "regional center" is connected to one of higher rank by what is known as a final trunk group (shown by the solid lines). Each regional center is connected by a final group to each other regional center in the United States. In addition, high-usage trunk circuits (shown in Fig. 1 by dashed lines) are employed between the various switching systems as determined by economic studies. With switching machines capable of automatically selecting as their first choice a direct trunk, if available, and of making successive choices involving an increasing number of links, the number of links in a connection may vary between one and eight for any two customers, in the same regional-center area. For calls between customers in different regional-center areas the number of links may vary between three and nine. The maximum use of high-usage trunks, as permitted by economic studies, results in a reduction in the number of links in a telephone connection and thereby in improved transmission performance.

Fig. 2 shows the present view of the location of the ten regional centers (RC) in the United States and of the two in Canada. This indicates one addition and the relocation of three others as compared to the previous view. The number and location of regional centers are based on studies to obtain an approximate cost balance between intertoll trunk and switching costs. These studies are a continuing project and changes and additions in the number and location of regional centers or other switching centers will be made in years to come. The transmission plan must, therefore, be reviewed continuously and be flexible enough to follow the indicated economic changes. The Canadian and United States switching plans are integrated by means of intertoll trunks between the two Canadian regional centers and some of the regional centers in the United States. Full interconnection on a final basis is at present uneconomical so that for some calls between Canada and the United States there will be ten links involved in the connections. This results in RC-RC-RC connections for those cases where final groups have not been provided.

Basic Transmission Considerations

Before discussing the various switching systems employed it will be desirable to review briefly the following most important transmission considerations involved in nation-wide switching of intertoll trunks.

1. Crosstalk.
2. Noise.
3. Distortion (frequency bandwidth).
4. Echo and echo control.
5. Singing or near singing.
6. Intertoll trunk losses (deviations from assigned losses).

The first two factors, crosstalk and noise, are controlled by the design of the intertoll trunks. This involves primarily the spacing of carrier and voice-frequency repeaters. It is important that the fundamental design of the system meets the transmission requirements for its

Paper 58-5, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted June 7, 1957; made available for printing October 11, 1957.

O. F. Wallman is with the American Telephone and Telegraph Company, New York, N. Y.

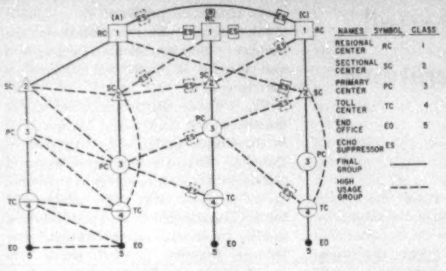

Fig. 1. Interconnection of high-usage and final intertoll trunk groups

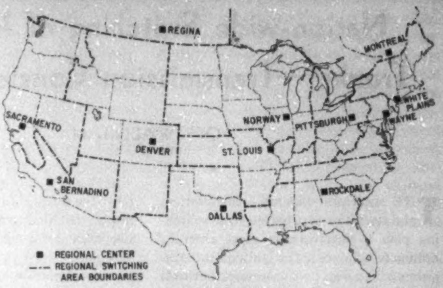

Fig. 2. Regional area boundaries: tentative April 1957 view of 1965 arrangements

intended use in the nation-wide layout. The design of the switching system components, including wiring and cabling, must be such as to provide negligible contribution to over-all noise and crosstalk.

Amplitude (or transmission) distortion is also a fundamental consideration in the design of a carrier or voice-frequency system. This involves the provision of sufficient bandwidth of the channel filters and associated terminal equipment to realize the full capabilities of the telephone instruments. An important factor in this respect is to hold the amount of office-type cable (series or multiple) to reasonably short lengths. The amount contributed by any one switching office may be relatively small but the accumulative effect of the wiring in each of the switching offices shown in the built-up connections in Fig. 3 may result in considerable transmission distortion in long built-up connections unless careful attention is given to the cabling lengths in the individual offices. Office-type cabling generally has a high mutual capacitance (about 0.125 microfarad per mile). Tests indicate that an office (900 ohms impedance) whose cabling (series and multiple) measures 0.07 microfarad will have a loss 1 db (decibel) higher at 3,000 cycles than at 1,000 cycles on a switched connection.

Echo and Echo Control

Tests indicate that people's tolerance to echo depends upon the loudness of the echo arriving at the talker's ear and the amount the echo is delayed with reference to his direct speech. There is also a relatively wide difference between individuals as to the relative loudness and delays which they will tolerate. The average tolerance to echo obtained from tests under controlled conditions are listed in Table I.

These values form the basis of present designs for intertoll trunk losses. Recent tests made to confirm these values indicate that present-day customers may be somewhat less tolerant to talker echo, particularly at the longer delays, than the figures indicate. However, with the use of carrier facilities on all final route trunks the round-trip delay on calls entirely on one regional center area will be less than the maximum of 45 ms (milliseconds) expected under the plan. This will introduce some margins that should permit the continued use of the present design factors.

Echo control is accomplished on all interregional telephone connections by the use of echo suppressors on all regional center-regional center trunks and on the high-usage interregional trunks as required. On switched connections entirely in one regional area the assigned trunk losses must be large enough to control echo without the benefit of an echo suppressor. This is illustrated in Fig. 3 by the switched connection between telephone *A* and telephone *B*. It is an interesting fact that from an echo standpoint the echo paths returning from the most remote points are the most important since they have the longest delays (round-trip transit time). The various talker echo paths in this connection for customer at telephone *A* together with their round-trip delays are shown in Fig. 4. They range from 1.9 ms for path *A* to 25.9 ms for path *D*. Path *D* is the controlling path if the return losses of the adjacent primary center (PC) meet the objectives outlined later in this paper. This illustrates again that the transmission considerations relating to nation-wide switching must be based on coordinated teamwork since the terminal return losses at telephone *B* have a considerable effect on the talker echo of the customer at telephone *A* and vice versa.

Table I. Average Tolerance to Echo

Round-Trip Delay, Ms	Average Tolerance to Echo-Loss Required in Echo Path, db
0	1.4
20	11.1
40	17.7
60	22.7
80	27.2
100	30.9

An echo suppressor is a voice-operated device that can be inserted in a 4-wire trunk circuit to control echoes on a telephone connection. For example, when the customer at telephone C (Fig. 3) talks, his speech power operates a relay chain in the suppressor which introduces a loss of about 40 db in the oppositely directed transmission path. The loss is under control of a differential balance arrangement so that each customer can break in and interrupt the speech of the other if he raises his voice as to have his speech power about 5 db higher than that of the other customer at the echo suppressor input. The loss must remain in the transmission path long enough after he pauses in his speech to attenuate his return speech (echo) that is reflected across the 2-wire branch of the 4-wire terminating set of the intertoll trunk at the toll center (TC) of customer *A*. This is accomplished by the use of adjustable slow-release relays. The length of time this loss remains in the opposite transmission path is called echo suppressor "hangover" time. In the connection shown this is approximately 57 ms. In the connection shown the echo suppressor is located at the regional center nearest customer *C* and when the customer at *A* talks the hangover can be as low as 12 ms. However, the hangover adjustment on each echo suppressor must be long enough to attenuate the talker echo on any connec-

tion to which it may be switched. Tests indicate that best results in the operation of echo suppressors are obtained if the hangover adjustments do not exceed a maximum of 70 ms. For the maximum geographical distances involved in the switching layouts of the United States and Canada this can be accomplished by employing an echo suppressor on each end of the longer RC-RC circuits and interregional high-usage circuits. When two echo suppressors are employed in this manner the suppression circuit in one direction of each echo suppressor is disabled. This permits a reduction in hangover adjustment equal to the round-trip delay (milliseconds) of the RC RC trunk involved.

Singing or Near Singing

In the built-up switched connection of Fig. 3 between telephone *A* and telephone *C*, the echo suppressor will control the echoes. It can, however, be unstable from a singing or near-singing standpoint. Singing can occur around any two 2-wire paths in the connection. Singing occurs if at any one frequency the losses around the singing path become less than the gains. Tests indicate that singing will most generally occur at the low or high frequencies of the voice-frequency band (300 to 3,000 cycles). Tests also indicate that built-up connections become unstable about 6 to 10 db before singing actually occurs, particularly if the instability occurs at frequencies in the lower part of the echo band. In talking over such a connection it sounds like talking into an empty barrel and is often identified as "hollowness."

In order to control both echo and singing it is necessary to set up certain objectives for return losses at the toll centers and at the 2-wire switching offices. It has generally been assumed that the frequencies important from a singing standpoint extended from 200 to 3,000 cycles. This was generally true for voice-frequency intertoll trunks. Recent tests have shown, however, that for carrier facilities the channel band-pass filters tend to introduce more loss at 200 cycles than at 1,000 cycles. This effect makes singing more likely to occur in the frequency range of 300 to 3,000 cycles on switched intertoll connections. It will be noted from Fig. 3 that there are no singing or echo return paths at the 4-wire switching offices. All the losses and return losses can be represented by averages and their variability from these averages or standard deviation. In order to assure freedom from objectionable echo and stability, from singing or near singing on a very high percentage of switched connections, objectives have been established as given in Table II.

Table II. Objectives for Return Losses

	Terminal Toll Offices		2-Wire Switching Offices	
Return Losses	Avg, db	Standard Deviation, db	Avg, db	Standard Deviation, db
Echo (500 to 2500 cycles)	15	3	27	3
Singing (300 to 3000 cycles)	10	2	20	3

The various potential singing paths in the interregional connection shown in Fig. 3 are outlined in Fig. 5. Here again, as mentioned previously for the echo paths, it is important that the return losses in the singing frequency range meet the objectives. If they do, the controlling singing path will most probably be path *A* since the terminal return losses are lower than those on switched connections at the intermediate 2-wire switching offices.

Intertoll Trunk Losses: Deviations From Assigned Losses

Fig. 3 shows the assigned losses of typical lengths of carrier channels that might be involved in a switched connection comprised of final group trunks. Routine tests indicate that these circuit losses vary from their assigned values. A number of factors contribute to the deviations, such as imperfect regulation, error in original line-up, etc. The design factors on which these assigned losses are based assumed that by routine measurements and adjustments together with improved maintenance techniques, the one-way transmission variation could be held to a standard deviation not exceeding 1.0 db. Measurements also indicate that at least for some intertoll trunks the round-trip standard deviation is nearer twice than the 1.73 times the one-way deviation previously assumed. These losses and their

variations are very important in the results to be obtained in the nation-wide switching of intertoll trunks. On the basis of the losses indicated in Fig. 3 and the distributions, it will be clear that the individual links will be operating at gains instead of the losses indicated a considerable percentage of the time.

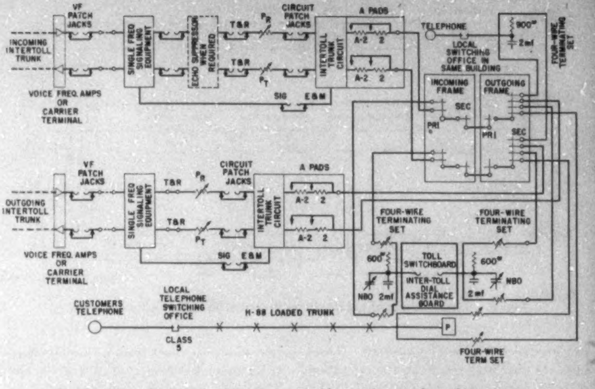

Fig. 6. Through and terminating connection for no. 4 type of switching system

Switching Systems

This paper discusses the transmission features of switching systems employed in the Bell System for nation-wide switching of intertoll trunks. There are other switching systems employed by the independent telephone companies not covered in this paper.[7]

FOUR-WIRE SWITCHING SYSTEM

Fig. 6 shows a schematic arrangement of trunk circuits switched through a 4-wire switching system of the no. *4* type. The sketch is shown on a line-per-pair basis. The 4-wire systems are located at the larger switching offices. On a through intertoll-to-intertoll switch there are no echo or singing paths in the switching office. Most of the intertoll trunks now consist of carrier channels which are of the 4-wire type (a separate channel for each direction of transmission). This eliminates the need for 4-wire terminating sets for intertoll-to-intertoll connections. The carrier system terminates in the voice-frequency (VF) patch bay for testing access to the carrier system independent of the switching system. Both intertoll trunks shown are equipped with a single-frequency signaling system employing a frequency in the voice-frequency band that can readily be transmitted over any of the message channels. It will be noted that it terminates in the trunk circuit by means of E & M signaling leads. This is standard for the Bell System and permits the intertoll trunks to be terminated in any one of the switching systems discussed in this paper. Channels of some of the carrier systems have signaling built into the channel terminals and they have E & M leads that co-ordinate with the trunk circuits associated with the various switching systems.

Carrier channels are inherently arranged to provide high transmission levels at the output of the demodulators. Advantage is taken of these levels in the 4-wire switching system to provide gain as required. This is accomplished by means of the switchable *A* pad associated with the trunk circuit as shown in Fig. 6. The *A* pad is divided into two sections. One section has a loss of 2 db and the other (*A*-2) db. In switching systems currently installed the (*A*-2) section is usually 5 db thereby making the total *A* pad 7 db. Each section is controlled by contacts of separate relays. As shown in Fig. 6, the entire *A* pad remains in the connection on each intertoll trunk on an intertoll-to-intertoll switch. The *PR* pad is adjustable in steps of 0.25 db to adjust the loss of each intertoll trunk to provide the specified loss from the switches in the remote office to the switches in the office shown in Fig. 6. This is known as via net loss (VNL) and is the lowest loss at which the trunk can be operated, limited by its inherent characteristic and the variations in return losses at the terminals and at 2-wire switching points. The *PT* pad is used to provide the proper level at the input of the various carrier or voice-frequency systems.

If an operator at some distant office desires assistance in completing a call she can be connected to an operator at the toll switchboard by dialing the proper code and the incoming trunk will be connected to the trunk to the toll switchboard as shown in Fig. 6. The assistance operator can complete the call by selecting a trunk to the incoming frame of the 4-wire machine which will connect to any outgoing trunk to the intended telephone upon receipt of the proper dial code. It will be noted that for the connection shown each trunk appears as a 2-wire trunk at the switchboard. The losses of the two 4-wire terminating sets are canceled by gain introduced by removal of the entire *A* pad of each connected intertoll trunk. The loss in each switchboard trunk is built out to a loss value of *A*. On the switch the loss is equal to $-A+A-A+A=0$. It will be seen that the connection through the switchboard does not introduce a loss penalty to the connection. It will be necessary, however, to build out the capacitance in both 2-wire switchboard paths to a uniform value and adjust the network building out (BO) capacitors across the compromise network of each 4-wire terminating set to the correct value based on return loss measurements. Two-wire switchboards are generally employed, since the operators can complete other calls when not occupied with assistance calls. At some of the 4-wire switching offices the assistance switchboard is of the 4-wire type with 4-wire cord circuits.

When the incoming intertoll trunk is connected to a switching trunk to the local office it connects to the 4-wire side of a 4-wire terminating set associated with the 2-wire loaded trunk to the local office. Since the 4-wire terminating set is connected directly to the loaded trunk a precision network can be used to match the loaded trunk and high terminal balance can be obtained so that gain can be introduced into the trunk by removing the entire *A* pad (7 db). Four decibels of this gain cancel the loss of the 4-wire terminating set and 3 db are available to offset some of the loss in the local trunk. In the connection shown in Fig. 6 the 24-gage *H88* loaded switching trunk to the remote class *5* office has a trunk loss of 6 db. It is connected to the switching office outgoing frame by means of a combined 4-wire terminating set and trunk circuit. It is arranged with a simplex mark so that when seized by an incoming intertoll trunk the entire *A* pad is removed and 3 db of the loss of the trunk are offset by the gain obtained from the *A* pad removal.

Fig. 7. Dial-to-dial intertoll connection through crossbar tandem showing supervisory and transmission paths

The net trunk loss is now 3 db instead of 6 db. If the switching trunk is terminated on a local switching machine in the same building as the 4-wire switching system only the 2-db section of the *A* pad is removed to cancel 2 db of the 4-db loss in the 4-wire terminating set. The 2-db remaining loss in the 4-wire terminating set acts as a 2-db equivalent pad required for return loss improvement.

Two-Wire Switching Systems

The economics of the no. *4* type of switching system favor its use in the larger switching offices. It is somewhat more expensive than 2-wire switching systems at those offices where the number of intertoll trunk terminations do not exceed about 3,000. Consequently, 2-wire switching systems are employed at the intermediate-sized and smaller-sized switching offices.

When 2-wire switching systems are employed, singing and echo paths are introduced in the switching office. Since any trunk must switch to any other, the most practicable way to handle the balance problem is to make all circuits uniform in impedance to permit a single value of compromise network. It is important, therefore, to give careful attention to the design of the various equipment components that are employed in the transmission paths. The following transmission requirements should be met if satisfactory results are to be obtained at 2-wire switching offices:

1. The 4-wire terminating sets must have a flat transmission-frequency characteristic in the useful transmitted voice band (300 to 3,200 cycles) in order to avoid undue transmission distortion in a switched connection. Two such 4-wire terminating sets are involved in an intertoll-to-intertoll switch at each 2-wire switching office.

2. Four-wire terminating sets must have an impedance (viewed from the 2-wire side) that closely approximates the compromise balancing network selected for the office.

3. All equipment and wiring used to establish the connection must make only a very small contribution to the impedance of the connection, for instance:

(*a*) All bridged impedances (across the transmission paths) must have sufficiently high impedance over the important voice-frequency band so that they do not appreciably effect the office return loss.

(*b*) Switching office wiring layouts should be carefully planned to keep the effect of the maximum series resistance of the wiring in the office path when two intertoll

Fig. 8. Connections through no. 5 crossbar switching system

trunk circuits are switched to a minimum. As a practical matter, the resistance is kept within the following values:

(1). 900-ohm switching office, 65 ohms.
(2). 600-ohm switching office, 45 ohms.

When the resistance is limited as in the foregoing, the office return loss paths in 2-wire switching offices can be maintained at satisfactory high values by making capacitance adjustments in the office wiring as discussed later.

Fig. 7 shows a schematic arrangement of the transmission and supervisory paths through the crossbar tandem switching system. This system is used at those switching offices where the ultimate number of trunk terminations is not expected to exceed its capacity. Fig. 7 is drawn on a line-per-wire basis in order to show more clearly the supervisory paths through the office. The crossbar tandem employs reverse battery loop supervision through the office and consequently the supervisory relay (CS) is bridged across a capacitor in the transmission path. This relay must, therefore, be designed to stand the supervisory current through its winding without appreciable change in its inductance. The crossbar tandem system does not employ a trunk circuit with repeating coils for impedance matching in the switching trunks to the local offices. As a result, the offices' impedance has been designed to be 900 ohms. Therefore, the 4-wire terminating sets associated with the intertoll trunks are designed to match the 600-ohm impedance of the carrier channels or voice-frequency amplifiers to the 900-ohm impedance of the 2-wire switching system. The office loop supervisory current is fed through the 2-wire windings of the terminating set. The design of the coils in the 4-wire terminating set must be such as to carry the supervisory current (30-mil) without appreciable change in inductance.

In the connection shown in Fig. 7, the incoming trunk is connected to office switches by the operation of relay *D* in the intertoll trunk circuit. The connection at the office link frame is made to the outgoing trunk through contacts of relay *D1* in its intertoll trunk circuit. It will be noted that adjustable building-out capacitors (BO, BO*1*, and BO*2*) are provided in the individual branches of the transmission paths so each can be built out independent of the other.

The return loss is measured across the jacks on the 4-wire side of the terminating set associated with the incoming intertoll trunk. The jacks on the 4-wire side of the 4-wire terminating set associated with the outgoing trunk are terminated in 600 ohms. This is done to limit the return loss measurements to the switching office under test. For measurement of return loss across the jacks of the 4-wire terminating set in the outgoing intertoll trunks the testing procedure is reversed. To obtain the return loss for office balance evaluation it is necessary to subtract the loss of the *PT* and *PR* pads and the losses of the 4-wire terminating set from 4-wire to 2-wire and from 2-wire to 4-wire from the measured values. This is most conveniently done by another return loss measurement with a short circuit temporarily placed across 2-wire side of the 4-wire terminating set. Return loss measurements are made on the office paths of each intertoll trunk in the switching office.

It will be noted in Fig. 7 that a 2-wire trunk is employed from the office link frame to the intertoll dial assistance switchboard. A 4-wire trunk is employed from this switchboard to the trunk link frame. This is done to permit satisfactory balances through the office on operator assistance calls as well as on calls directly through the switches.

Fig. 9. Through and terminating connections for step-by-step switching system

At some of the smaller switching offices where a single switching machine can handle both the toll and local switching requirements, the no. *5* crossbar switching system is employed. Fig. 8 shows a schematic arrangement of an intertoll-to-intertoll switch. This schematic is on a line-per pair basis. The incoming trunk is connected to the line link frame by the operation of relays (*CO*) (*RD*) and the nonoperated contacts of the *LT* relay. The switches close through to the trunk link frame where the outgoing trunk is connected through the nonoperated contacts of relay *LT*, the operated contacts of relay *RD* and the nonoperated contacts of relay *SLI*. The no. *5* crossbar system employed for toll switching has been designed for an office impedance of 600 ohms. The 4-wire terminating sets employed at this office have a 1-to-1 impedance ratio from 4-wire to the 2-wire side. The compromise balancing network consists of a 600-ohm resistance in series with a 2-microfarad capacitor. The various branches of the 2-way intertoll trunk circuits are also equipped with adjustable capacitors (BO*1*, etc.) to permit office paths capacitance adjustments to provide for the necessary high return loss similar to that previously discussed in connection with the crossbar tandem switching system.

At some of the switching offices, particularly primary centers, the step-by-step switching system was already in operation when the present nation-wide switching plan was devised. Since the step-by-step system employed in the Bell System does not have common control equipment it does not have the inherent capabilities of selecting high-usage trunks for alternate routing. However, from a transmission standpoint, the office echo and singing paths can be controlled by compact office layouts and office wiring balance work as discussed for the previously mentioned 2-wire switching systems. Fig. 9 shows an intertoll-to-intertoll connection through the step-by-step switching system. It will be noted that adjustable capacitors are provided in the various transmission paths through the office to permit the building out of the capacitance of the office cabling to uniform values as required. The nominal impedance of the step-by-step switching system is 600 ohms. The 4-wire terminating sets associated with the intertoll trunk circuits are of the type having an impedance of 600 ohms on both the 4-wire and 2-wire branches. The compromise networks are composed of a 600-ohm resistance in series with a 2-microfarad capacitor and are equipped with an adjustable network-building-out capacitor. It will be noted from Fig. 9 that it employs trunk circuits with E & M leads which connect with the standard single-frequency signaling system to transfer the necessary supervisory signals through the switching office. The step-by-step system employs simplex supervision paths through the office obtained from the center tap of inductors bridged across the transmission paths in the intertoll trunk circuits. Their inductance must be high enough so as not to alter materially the office impedance.

In the next 5 or 10 years most of the major switching offices now contemplated in the Bell System will be in and operating. Equipment is also being provided which should result in a large increase in the number of calls dialed by customers. On such calls where any number of links from one to nine or ten are connected together by switching machines, transmission troubles on a particular connection will be difficult to locate. It will be necessary, therefore, to design and maintain the individual components by means of initial and periodic tests that will insure satisfactory performance on a very high percentage of switched connections.

Only about half of the ultimate 300 major machine switching offices are now in operation. It is planned to obtain information on their performance by means of transmission and return loss tests. This information will be helpful in the design and operation of systems yet to be installed.

A fairly high percentage of intertoll trunks are now operating at the low losses indicated in Fig. 3. A considerable number, meeting the new loss objectives, are added each year in connection with the addition of new switching offices or rearrangements. It is believed that the losses shown are about as low as can be reached in the present state of the art. However, if further experience indicates that they can be lowered it will be done.

The transmission engineer's dream is to have zero loss on all connections regardless of the number of links in tandem or distance involved. This cannot be achieved in the immediate future but with new instrumentalities and new developments it should be possible to approach nearer and nearer to the ultimate objective. In the meantime, he is striving to operate all existing plants to insure the best possible transmission on all switched connections.

Discussion

Arthur F. Rose (American Telephone and Telegraph Company, New York, N. Y.): Mr. Wallman's paper and the related papers of Bogan[1] and Speake[2] must be considered as a whole to appreciate the variety of problems involved in giving good nation-wide toll telephone service.

Mr. Wallman's paper emphasizes the problems at the intermediate switching points where it is desirable to eliminate in so far as practicable the echo and singing paths. If economics would permit, all intermediate points would be switched on a 4-wire basis and this problem would disappear, but the practical conclusion is that we cannot afford this luxury. Many of the smaller offices will continue on a 2-wire basis indefinitely, and Mr. Wallman's paper shows how their echo contributions can be made negligible by proper design and engineering procedures.

However, the point I wish to emphasize is that it is not enough to do this initially, but eternal vigilance is required to insure it remaining so. Every time new switchboard positions or multiple are added at a 2-wire switching point, checks should be made and building-out capacitors adjusted if necessary to avoid the gradual erosion of the initial high office-return loss.

The maintenance costs involved in this continual checking offset to some extent the first-cost advantage associated with 2-wire switching in the smaller offices. However, the practical approach is not to try to have our cake and eat it too, but to carry out honestly the commitments which we tacitly assumed when we elected to use 2-wire switching as the proper engineering solution in a particular switching center. As time goes on and new plant personnel take over the office, it will be easy to forget the need for spending this maintenance money in those cases where first-cost savings may have been substantial.

In an unpublished paper by J. N. Petrie it was claimed that the well-known "tail-eating" scheme avoids the balance worries inherent in 2-wire switching systems described by Mr. Wallman and is simpler than the full 4-wire treatment used in the Bell System. From a practical standpoint again, continuing maintenance attention should be balanced against first cost savings and permanent good results will not be attained without checks from time to time.

2. STUDY OF RETURN LOSSES ON LOADED TRUNK CABLES AND METHODS TAKEN TO IMPROVE THEM, G. H. Speake. *AIEE Transactions*, vol. 77, pt. I, May 1958, pp. 201–04.

E. A. Bourne (Bell Telephone Company of Canada, Montreal, Que., Canada): As Mr. Wallman has pointed out, co-ordinated teamwork among operating companies and suppliers is necessary for satisfactory performance on toll connections. The aim of this discussion is to enlarge on this aspect, drawing upon the Canadian switching network to illustrate the need.

In Canada, our major toll switching centers utilize equipment manufactured by several suppliers and are operated and maintained by various fully independent organizations. For example, of nine of our largest cities two are equipped with Bell System *4A* crossbar, two will use General Telephone *FW-1* equipment, three have Siemens auto toll equipment, and two are being equipped with Bell System crossbar tandem. Eight are major switching centers and are operated by six independent organizations. Interconnection of these systems could result in compromised transmission objectives if any system is permitted to introduce appreciable echo or singing paths. In the case of echo, the results of poor return loss are not apparent to the customer at the point of poor return loss, but indeed to the customer at the other end of the connection, perhaps 1,000 miles away. It is evident that the long-distance customer is not the exclusive responsibility of one company but the joint responsibility of all and it is for this reason that the adoption of uniform transmission standards by suppliers and operators is necessary.

Mr. Wallman has dealt mainly with switching equipment in use in the Bell System. Another type of switching system, very much on the Canadian scene is the "tail-eater," a type of 4-wire switching equipment manufactured by the Automatic Electric Company and by Siemens Brothers of England. The transmission performance of the Automatic Electric *FW-1* system has been covered by Dr. Molnar (see reference 7 of the paper). Siemens equipment has been tested from an office balance standpoint by the Manitoba Telephone System and results indicate good performance in echo and singing ranges.

The Application of Negative-Impedance Repeaters on Long Rural Telephone Lines

H. T. UTHLAUT, JR.
MEMBER AIEE

PRESENT-DAY expansion of telephone service is at peak levels with no immediate end in sight, and benefiting by this expansion is an important segment of the United States—the rural area. Questions may be asked, "What's new about this?" or, "Rural telephones have been with us for years, so why the fuss?" True, there is nothing new in the concept of rural telephone service, but the present demand is at such levels that serious problems are presented to the telephone industry. The economic problem is one of real significance, but it is not discussed here. It is proposed to discuss, rather, the transmission aspects involved in extending this service to these areas.

Problem

Studies have shown that there is a great demand in rural areas where telephone service has not heretofore been provided. In those areas where the demand has been small, open-wire circuits have generally been adequate and satisfactory, both from a desirable transmission viewpoint and from a construction standpoint. The present large demand, however, dictates the use of cable facilities to replace the inadequate open wire, and requires the loops to extend to lengths unprecedented in normal exchange service. It is not unusual in present engineering of rural telephone service to encounter conductor loops well in excess of 100,000 feet from the serving telephone central office. When, as so often is the case, the demand is too small to establish economically a new central office and too great to allow open wire to be used, cable plant, with its resultant high attenuation, must be proposed.

New Types of Plant

The ever-increasing search for newer and better products is in "full swing" in all industry in the United States, and the telephone industry is no exception. In addition to the many electronic devices under development, new outside plant is also in evidence. Some of the more recently developed items include polyethylene-insulated conductor cable,[1] *B* rural wire (polyethylene-insulated pairs spiralled about a steel support wire), *B* underground wire (rubber-insulated pair of no. 16 American Wire Gauge copper conductors with a steel-armor and a neoprene jacket), and *C* rural wire (one pair of polyethylene-insulated copper-steel conductors suitable for extra-long-span construction). Because of the high dielectric strength of the insulating material, it is expected that troubles on these types of plant will be less than that now experienced on paper- and pulp-insulated conductor cable.

These new types of outside plant are answering many of the needs of the telephone engineer, and are being proposed in a great many of the rural projects now being engineered.

Transmission Limitations

Having been apprised of types of suitable plant, the engineer may now see that the demand for telephone service must needs be satisfied by use of cable plant in an appropriate size, ranging from as little as six pairs to as many as 101 pairs in most projects, and possibly even greater in others. From the commercial viewpoint, it is seen that the demand will be served by cable. From the viewpoint of the outside plant engineer, the new types of cable plant, for both aerial and buried use, seem to be satisfactory. In contrast, the transmission engineer views with concern the proposal of voice-frequency subscriber loops of 90,000 feet of cable plant and 20,000 feet of open wire extending beyond that. It is in this area of telephone engineering where the present resistance-design philosophy is not adequate.[2] The only practicable method of meeting the d-c resistance limits of the central office

Paper 57-391, recommended by the AIEE Wire Communications Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 7–11, 1957. Manuscript submitted January 3, 1957; made available for printing May 13, 1957.

H. T. UTHLAUT, JR., is with Southern Bell Telephone and Telegraph Company, Birmingham, Ala.

in these cases is normally to use the coarsest gage cable in general use, which in the telephone industry is no. 19 American Wire Gauge. Therefore, the transmission engineering design has been reduced to calculation of the proposed subscriber loop to determine if objectives are exceeded.

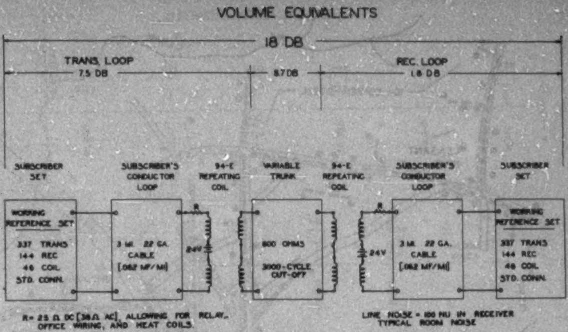

Fig. 1. Working reference system for specifying effective losses; equipment shown is of Western Electric nomenclature

When calculations of effective losses are made on these long subscriber loops, it is found that the use of cable plant of approximately 85,000 feet and open-wire extensions beyond this figure generally indicate that the loop, when compared with the working reference system described in Fig. 1, is about 0 db (decibels) at the end of the cable, if the cable is fully loaded at *H* spacing (6,000-foot intervals) with 88-millihenry loading coils, and the station sets use three cells of local battery and *HC5* receiver.

In this era of ever seeking to decrease the transmission losses on exchange subscriber loops (as well as on trunks), it is well to examine the transmission engineer's problem here. It has been his desire to establish the goal of maximum subscriber loops of −3 to 0 db (compared with the working reference system), and the closer to −3 db the better. Therefore, with the rural program being developed to a greater extent each day, the telephone engineers must maintain the high standard of transmission design to meet these established transmission goals. Cost studies prove that it is generally unsound economical practice to use coarse-gauge cable to reduce transmission losses. A better method of meeting these goals is by the use of *E*-type repeaters on these exchange loops. These repeaters are negative-impedance devices which are relatively inexpensive to install. They require no expensive filters or bypass signalling equipment. More information on this equipment is available in other literature.[3–6]

Examples

A typical example of an engineering design on which it was found necessary to provide for the use of repeaters is presented in the following.

Fig. 2 is a map of the area involved, showing the telephone demand and type of plant proposed. An estimate of the area's growth indicates that line requirements as shown on the map are expected. On the basis of the line requirements, the outside-plant engineer must propose the plant which is the economic choice. This plant is indicated on the map. Existing open-wire plant is also shown, and almost all of the existing feeder open-wire plant is proposed to be replaced by cable-feeder plant. The subscribers served by existing plant are not shown on the map, but an indication of the existing requirements, which are seven lines, is shown at the end of the cable.

Fig. 3 is a schematic diagram which shows the specific design of the facilities proposed to serve the demand in the area. It is this schematic which the transmission engineer will examine closely to assure that the design meets the prevailing objectives. In actual practice, more information is added to this schematic, such as pairs being distributed beyond the load points, and pairs cut dead to prevent excessive multiple beyond the location at which they are distributed.

The following items are included in the examination of the design:

1. Resistance check for supervision limits as shown in Table I. With use of proper types of central-office equipment to extend signaling ranges, this portion of the design is satisfactory.

2. Load-coil spacing on *H* design, as shown in Table II. Deviation of the average spacing from standard (6,000-foot) spacing is 10 feet or 0.2%.

This design meets a reasonable objective in subscriber-loop loading; i.e., average spacing within 2% of the standard 6,000-foot spacing, individual sections within 3% of the average of the design, and average deviation within 1.2% of average section.

3. Distribution of fully loaded pairs in proper zones. Combined with this part of the design is the use of a reasonable amount of multiple tap, taking into consideration both the transmission penalty incurred by excessive amounts and the need to increase it to an amount suitable for obtaining a satisfactory percentage of 8-party stations per line.

4. Determine the effective loop loss (compared with the working reference system) using the data shown in Table III for local battery station equipment, as follows:

a. Losses
   $(3)/(1) = 1.3$ db
   $(2) = 30.7$ db
   Miscellaneous losses $= 0.5$ db (loss for transformers, drop, etc.)
      Total losses—32.5 db
b. Gains
   Loop-loading gain $= 1.5N - 1.5$, for 22, 24, 26 gage (N = no. of load coils)
   Loop-loading gain $= 1.1N - 1.5$, for 19 gauge
      Total gain $= -17.3$ db
c. Corrections
   Correction for local battery loop $= -11.0$ db
   Correction for more efficient transmitter and receiver, and for three cells of local battery $= -2.0$ db
   Gains are shown as negative and losses as positive.
d. Totals
   Total losses $= +32.5$ db
   Total gains $= -30.3$ db
      Loop loss $= +2.2$ db $(T+R)/2$

In the examination of this design, the transmission engineer has determined that the only unsatisfactory aspect is the transmission loss. The means of reducing the transmission loss have been discussed previously. The method of reducing this loss by replacing existing cable with larger gage is a possibility. It would also be possible to consider use of even a coarser gage, such as 16 gage. These two methods are generally prohibitively costly, however, and another solution should be explored. This leads naturally to consideration of the use of an *E*-type repeater.

Considerations in Repeater Design

All the aspects in the application of the *E*-type repeater are not discussed here. Suffice it to point out that this layout

lends itself adequately to the use of a repeater. Where there is a well-planned utilization of cable gages and a properly designed loading layout, a high structural return loss may be expected with cable manufactured to stringent tolerances. An *E-2* repeater is chosen over the more expensive *E-23*, because adequate gain to meet present objectives generally may be obtained from the former. To meet future objectives, it may be possible to consider adding the *E-3* element to the proposed *E-2* repeater.

As discussed in the foregoing, the reference point of a 0-db $(T+R)/2$ loop was established as the point beyond which loops should have a repeater placed in the circuit at the serving central office. This could just as arbitrarily be chosen at −1 db or −2 db, which would produce even better transmission on the subscriber-loop plant. There are several limiting factors on this decision, however, and the most difficult one to satisfy is the supply situation. For the next few years there will not be enough repeaters available to hold all subscriber loops as low as −2

db. Therefore, it appears that the use of the 0-db point is more realistic. For the example used in the paper, the requirements for repeaters on loops greater than 0 db $(T+R)/2$ have been indicated. This point is located at approximately 84,000 feet from the central office.

For the layout shown in Fig. 3, a repeater gain of 3.5 db may be reasonably expected from design calculation. With this gain, the effective subscriber loop will be -1.3 db $(T+R)/2$ compared with the working reference loop. Therefore, by using an *E-2* repeater in the circuit, the loss is within a realistic transmission design objective, thus rendering satisfactory a subscriber loop which would have been beyond the boundary of good engineering design.

As an example of how some of these considerations find their way into the design of rural telephone plant, there have been nine rural projects in the Alabama division of the Southern Bell Telephone and Telegraph Company which have specified *E-2* repeaters on certain loops. A total of over 110 repeaters have been required on these projects which had effective subscriber loops from $+0.7$ to $+3.6$ db $(T+R)/2$. Nominal gain of *E-2* repeaters on these loops were 3.5 to 4.0 db, with the resulting calculated design of better than 0 db $(T+R)/2$ on all projects. In addition to these projects where definite plans have been made for repeaters, others are under consideration to bring losses within reasonable objectives. No figures are available as to the possible number of repeaters required for these additional areas.

Summary

Today's rural area is much different from that known by our forebears. One thinks fondly of a past era which included the kerosene lantern, wood-fired range, kitchen washstand and, if it were a progressive area, a farmer telephone line, but certainly no one would be willing to exchange the modern electric lamps, electric household appliances, plumbing systems, and adequate telephone service for the antiquated items of yesteryear.

After examination of the problem presented by extension of telephone service into the rural area, it is seen that in many

cases the subscriber-loop loss could easily exceed desirable transmission objectives. In discussing the provision of adequate telephone service in these areas, the author has attempted to show how the *E-2* repeater can be a valuable tool in the reduction of loop losses.

Suitable plant for providing an adequate quantity of service is available and is being used. The need and demand for service in the rural area is often such as to make it economically attractive to provide it. In providing it then, the problem is that of making the quality agree with the progressive quality of other services available to those in rural areas.

Conclusions

What will be the ultimate transmission objective for subscriber loop losses? Each individual's ear will dictate the answer. A recent cartoon quoted an old man saying, "Us oldsters born before 1900 always holler when we talk on the telephone." The aim today is to design all telephone circuits so that one does not need to "holler" to be heard, and the practice of good circuit design is being carried out in the telephone industry. Progress is indicated by the fact that those who were born in more recent years not only do not "holler," but even whisper when they talk over the telephone and expect to be heard. This quality of service must be provided. Therefore, for the next 10 years −3 to 0 db may be adequate, provided trunk losses are reduced adequately. On the other hand, maybe these loops should be somewhat better, such as −5 to −1.5 db. The question posed will have to wait until time allows the communications engineer sufficient knowledge to examine the "crystal ball" with a more practiced eye. Until that time he must make plans to reduce losses to acceptable values consistent with the exercise of proper caution for an economically sound design. In this respect, it appears that the *E*-type repeater will be in increasing evidence in the long subscriber exchange loop in the immediate future.

Airborne Teletypewriter AN/AGC-1

RICHARD A. MICHALS
NONMEMBER AIEE

Synopsis: The transmission of information by teletypewriter means has proved itself, as shown by the number of civilian and military networks now in operation. The advantage of this method over voice lies in its reduced bandwidth and the production of printed copy. The teletypewriter code also allows specialized data-transmitting techniques to be used; the printed copy eliminates operator stand-by time. It was natural that the Air Force would want to extend its teletypewriter network to include its aircraft. Kleinschmidt Laboratories was awarded the contract to develop such an airborne teletypewriter, known as the *AN/AGC-1*. Basically, the Air Force required a send-receive type of teletypewriter incorporating a recorder-reproducer device for information storage, and a selective call system. This paper presents the results of the developments leading to the design of such a teletypewriter.

THE REQUIREMENT for aircraft installation and operation imposed many problems not normally encountered in teletypewriters. Among these were: 1. Minimum weight and size. 2. Available aircraft space, which required that the set be broken up into major components. 3. Minimum operator time. 4. Aircraft environment. These requirements indicated a new approach to the problem.

The standard printing mechanisms were much too bulky and an isolated unit would be difficult to control. The punched tape method of storing messages had to be changed since it required operator handling. The standard keyboard, receive-transmit mechanism, and control unit would also have to be changed if changes were made in the printer.

It was felt that electronic techniques could be used to replace many of the mechanisms required in a teletypewriter. For example, during receive operation, the changeover of electrical information into mechanical form could be accomplished at the printer selector shaft rather than at the selector magnet. The handling of the information in electrical form, rather than mechanical, reduces the problems.

By using electronic techniques it is possible to build an airborne teletypewriter capable of meeting the requirements of the Air Force. In general, the Air Force required that an airborne teletypewriter provide the following:

1. A page printer capable of operating at 60 WPM (words per minute), alphabetic only.
2. The separation of the set into four major components, known as keyboard, printer, terminal unit, and control panel.
3. All units to be interconnected by means of wires only.
4. A call system for elimination of local traffic.
5. A storage unit to store keyboard information for later transmission at 60 WPM.
6. Operation on 7.5-unit start-stop teletypewriter signals.

Fig. 1 shows the units comprising the *AN/AGC-1*. The purpose of each of the units is as follows:

The control box allows selection of all the operating modes of the teletypewriter. It contains the function switch, power switch, call IN-OUT and rewind indicator light.

The keyboard converts the operator information into teletypewriter form.

The printer converts teletypewriter information into a printed copy.

The terminal unit contains all the electronic hardware for accomplishing the translations.

The first items to be designed were the page printer and the storage unit. The criterion used in their design was to keep the handling of information in mechanical form to a minimum. From these units the rest of the electrical design evolved.

Printer

After an investigation into the various ways of accomplishing the printing, the

Paper 58-47, recommended by the AIEE Telegraph Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted October 14, 1957; made available for printing November 15, 1957.

RICHARD A. MICHALS is with Smith-Corona, Inc., Highland Park, Ill.

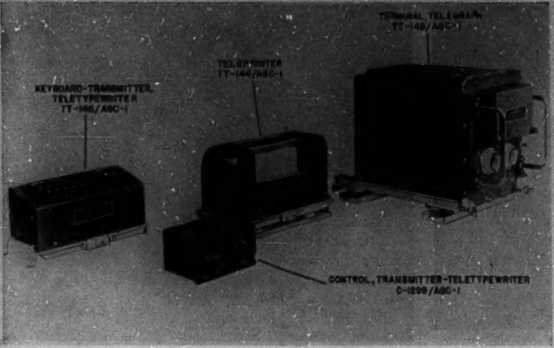

Fig. 1. Airborne teletypewriter set AN/AGC-1

typewheel method was decided upon. In this method, alphabetical letters are engraved on the periphery of a $1^1/_2$-inch-diameter wheel, which is positioned for the correct letter. The wheel is then made to slide on a square shaft; thereby a line of letters is obtained. Pressure-sensitive paper is then held in front of the typewheel, and a print-hammer blow causes the selected letter to be impressed on the paper. Fig. 2 shows the typewheel, square shaft, and print hammer. The paper is held between the print hammer and typewheel.

The positioning of the typewheel is done by a stop pawl engaging a tooth on a ratchet wheel. The ratchet wheel is fastened to the square shaft, along with wipers that act on a printed circuit matrix. The stop pawl is operated whenever the output from the matrix indicates that the desired letter is in position. Fig. 3 shows the stop pawls, the electromagnets for operating them, and the ratchet wheel. The ratchet wheel has 16 teeth; 32 positions are obtained through the use of two stop pawls.

Fig. 4 shows the printed circuit commutator. The commutator works into a diode matrix which receives information from the terminal unit. When a selection is to be made, the square shaft is rotated, which in turn causes the wipers to scan across the printed circuit segments, until a position is reached that corresponds with information fed into the matrix. At that time, the stop pawl is operated and engages a tooth on the stop wheel. This causes the square shaft to stop rotating, also stopping the typewheel which now has the desired letter in front of the print hammer.

Fig. 4 also shows the mechanism for causing the typewheel and print hammer to space or to line return; the paper-to-line feed; and the automatic line return, the line feed, and the printer hammer to operate.

The complete cycle of the printer is:

1. Drive motor shaft is disengaged by positive clutch.
2. Information is supplied to the printer matrix.
3. The printer cycle is started by engaging the positive clutch; this is accomplished by energizing an electromagnet, which also causes the release of the stop pawl, if one is engaged.
4. The engagement of the positive clutch causes the square shaft to rotate.
5. Wipers scan printed circuit segments.
6. Output of matrix indicates when wipers have reached segment corresponding to information supplied to matrix.
7. Matrix output energizes one of the stop pawls.
8. Stop pawl engages tooth on ratchet wheel.
9. Square shaft is stopped; typewheel is positioned according to information fed into matrix.
10. The print hammer is operated.
11. Typewheel spacing and/or line feed and line return mechanisms operate.
12. Positive clutch disengages drive motor shaft. Printer then waits for next cycle.

The square shaft is rotated at 600 rpm

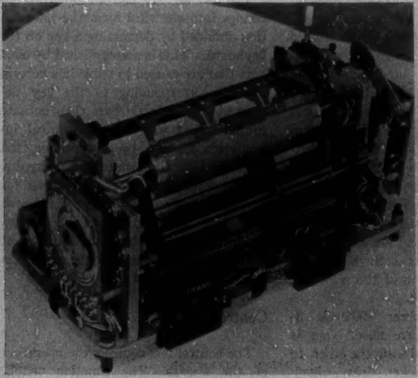

Fig. 2. View of printer with cover removed

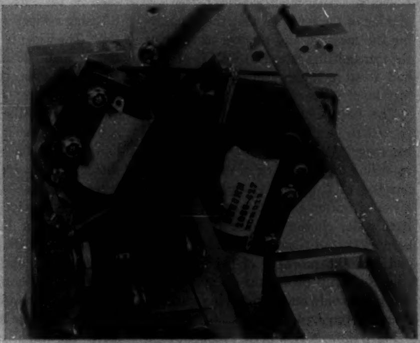

Fig. 3. Stop-pawls, electromagnets, and ratchet wheel

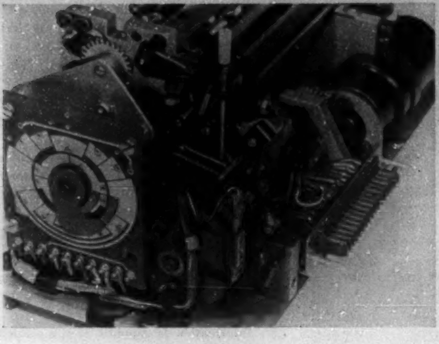

Fig. 4. Printed circuit commutator and mechanisms

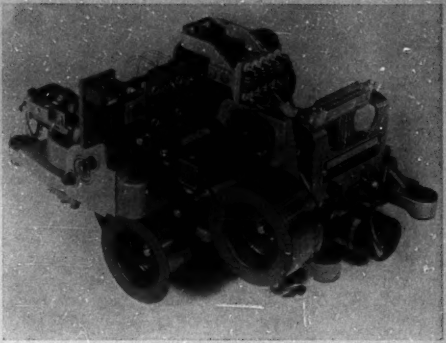

Fig. 5. Magnetic tape recorder

when it is making its selection. The time allowed for the stop pawl to operate is approximately 4 milliseconds. A total of 135 milliseconds is used for printing and the completion of all mechanical functions.

The advantages of such a printer lie in its small size and the ease with which it may be controlled. Its present size is $5^1/_4$ by $5^5/_{16}$ by 11 inches and its weight is 8 pounds. Wires connected to it supply signals for the matrix, mark and space stop-pawl electronmagnets, the positive-clutch electromagnet, and power for the drive motor.

Magnetic Recorder

The storage of teletypewriter information presented several interesting problems. The device had to be capable of storing a message as typed on a keyboard, resetting itself rapidly to the beginning of the message, and then supplying the message any number of times at the transmitting rate of 60 WPM. It also had to store a new message upon completion of a previous message.

The best solution to these problems proved to be the use of a magnetic tape recorder. Magnetic tape allows the recording and playback of messages any number of times. The tape used was made of flutter valve stainless steel, one inch wide, chosen because it could be accurately positioned after long usage, and had the property of being able to wind itself up on a take-up spool. By this means only one tape driving sprocket wheel is required.

Fig. 5 shows a view of the magnetic tape recorder used. The tape may be seen coming off the tape feed spool, passing through the erase coil, passing under the playback-record head and onto the tape sprocket drive wheel, and going to the tape take-up spool. Also shown is the head shuttle arm.

The method used for depositing the bits of information on the tape is to scan the width of the tape. A magnetic recording and playback head is made to travel rapidly across the width of the tape, then to return back to its starting position on the edge of the tape.

This type of operation allows the magnetic head to rest on one edge of the tape during any rewind or waiting-for-information time. Scanning of the magnetic head across the tape is done only when it is desired to record or play back information.

The storage and playback of the five bits (Baudot code) of teletypewriter information requires the separating of each of the bits. This is accomplished by using a wiper which scans a commutator. The wiper is mounted to move with the magnetic head. As the head sweeps across the tape, the wiper moves across the commutator segments, thereby separating each of the bits. To record, voltage information is supplied to the commutator and the recording head is connected to the wiper. For playback, the output of the head amplifier is connected to the wiper, and the commutator segments to a buffer storage. Fig. 6 shows a block diagram of the recording and playback circuits.

Two 1/150-horsepower 400-cycle 3-phase drive motors are used. One is used to cause the head scan, the other, to drive the tape sprocket drive wheel. This latter motor is reversed when it is desired to rewind the tape. All the motors operate through friction clutches. The cycling of the recorder is controlled by an electromagnetic latching mechanism. Releasing the latch allows the head to scan across the tape and to return, and causes the tape sprocket wheel to space the tape. At 60 WPM, 294 inches of tape are required for a storage time of 10 minutes.

This design has resulted in a rugged storage unit for recording and playback of binary information. Because it is mounted with electronic tubes it had to be capable of operating at a temperature of 95 degrees centigrade. It is now being used in other systems requiring these capabilities.

Keyboard

The purpose of the keyboard is to change into electrical form the information obtained by depressing a key on the keyboard. This is accomplished by code bars that are caused to move in a certain manner corresponding to the key depressed. These code bars then actuate contacts that will supply electrical information for use by the printer, the recorder, and the transmitting circuits. The code bars are counterbalanced for operation under conditions of extreme vibration. Included in the keyboard is a locking mechanism that is used to prevent the operator from exceeding the maximum transmitting speed of 60 WPM.

Control Box

The control box controls the operation of the system. The function swtch. determines the mode of operation, i.e. transmit-store, transmit-keyboard, re-

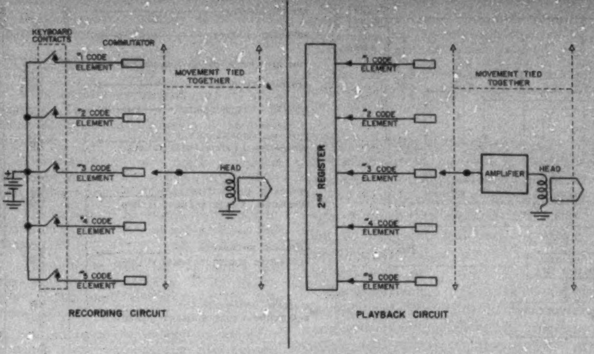

Fig. 6. Block diagram of recording and playback circuit

ceive, rewind, and store. The call switch allows the operator to bypass the call system and allows him to print all messages that are received. The power switch controls all the voltages going to the system. The rewind light indicates when the tape in the storage unit is in its fully rewound position.

The modes of operation of the control box are:

Transmit-store: The teletypewriter set will automatically transmit any message previously recorded on the recorder. At the end of message the set will automatically go into "receive" condition. A page copy of the message is also printed.

Transmit-keyboard: Transmission of messages is made directly from the keyboard and is monitored by the printer.

Receive: With the call switch in the out position, any messages received from the radio equipment will be printed. With the call switch in the in position, only messages preceded with a call will be printed.

Rewind: The magnetic tape recorder is operated to rewind the tape to its starting position. When the tape is in this position, the rewind light will light.

Store: A message will be recorded on the magnet recorder by operating the keyboard. The recorded message will not be transmitted; the printer will monitor the recorded message. If a message containing a call is received, the keyboard will automatically lock up, and the printer will print the received message. After the received message is completed, the keyboard will unlock and the recording may be resumed.

Terminal Unit

Almost all of the electronic circuits for operating the teletypewriter are contained inside the terminal unit. The magnetic storage unit is also housed in the terminal unit. The dimensions of the outer case are $10^3/_4$ by $10^1/_8$ by 15 inches, and the weight of the unit is 29 pounds.

Fig. 7 shows a view of the terminal unit removed from its case. The placement of the storage unit and the three subchassis may be seen. On the front panel is the call patch box and the connectors used in supplying signals to and from the terminal unit. Under the subchassis location are the relays and tantalum capacitors (used for filtering the power supply). Under the storage unit location are the 400-cycle power transformer, the silicon rectifiers and voltage-regulator tubes, the reed oscillator, and the polar relay.

All the subminiature tubes are mounted on the three aluminum subchassis. Resistors and capacitors are wired into the circuit by means of teflon-insulated stand-offs. For servicing, these subchassis may be removed from the terminal unit and repaired on the bench.

The circuits contained inside the terminal unit are used to accomplish the functions normally done mechanically. The most important of these is the generation of an accurate sequential signal. This is used for generating the sequential signal for transmitting, and for sensing the incoming sequential signal code elements. This is accomplished by an 8-tube linear ring counter driven by a time base.

Fig. 8 is a block diagram of the transmit-keyboard circuit. It consists of the following:

1. A reed-controlled oscillator operating at 272.7-cps (cycles per second).
2. First divider which is driven by the 272.7-cps oscillator and divides to 90.9 cps.
3. Second divider, driven by the first divider, dividing to 45.45 cps except during the time the no. 7 ring output is energized. At this time the output is 90.9 cps.
4. Ring counter distributor.
5. Gating circuit controlled by keyboard for forming sequential signal.
6. Polar relay for output.

A cycle of operation is as follows:

1. Ring counter is normally at its rest

5. Second register: storage of code elements for use by printer.

A cycle of operation is as follows:

1. Ring counter is normally at its rest position. The time base for driving the distributor is blocked by action of the start gate tube.

2. The transition from mark to space caused by a start pulse being received is used to start the time base.

3. The time base drives the distributor in synchronism with the incoming sequential signal.

4. The outputs from the distributor are used in the coincidence amplifier to determine the mark condition of the five incoming code elements.

5. Output from the coincidence amplifier is stored sequentially in the first register.

6. After the five code elements have been stored in the first register, they are transferred simultaneously into the second register.

7. The second register supplies the printer matrix with information which it then acts upon. The call system also receives its information from the second register.

8. The distributor comes back to its rest position, thereby stopping the time base. The cycle is completed.

The formation of the sequential signal for transmit-store operation is much the same as transmit-keyboard. Information from the storage unit is fed into the second register, which then supplies the information the keyboard had been supplying. It is then handled in the same manner as the keyboard information.

The selective call system makes use of a straight counting circuit. If the counter completes its count before any resetting pulses occur, it activates the operation of the printer. These resetting pulses are caused by space signals which are always present in a message. The letters that the call counter will respond to are selected by means of the matrix box which is plugged into tube sockets wired for the desired letters.

Subminiature thyratrons are used to energize the recorder and printer-selector electromagnets. A beam power subminiature tube is used to energize the printer clutch electromagnet. This tube also extinguishes any printer selector thyratrons that might have been fired.

A total of 45 tubes are used in the system. Thirty-nine are subminiature tubes and six, miniature tubes. The system uses 120 watts of 400-cycle power and 60 watts of d-c power.

Conclusions

The use of teletypewriter equipment aboard aircraft will increase the reliability of long-range communications. It will also greatly reduce the operator's time for transmitting and receiving messages. These features are being required more and more in the newer aircraft.

Automatic Telegraph Switching System Plan 55-A

G. S. VERNAM
MEMBER AIEE

THE 200,000-mile private-wire network of the United States Air Force includes five Plan 51 switching centers in the United States, leased from The Western Union Telegraph Company. These centers are interconnected by trunk lines and each center has lines radiating to tributary stations in its area. Gateway centers near the Atlantic and Pacific coasts extend the network over radio channels to numerous Air Force installations overseas. This network has been in operation since February 1951. Satisfactory experience in operating this network, with its push-button-operated Plan 51 switching centers, has led the Air Force to request Western Union to engineer a fully automatic switching system for world-wide use. It is expected that automatic switching will increase the speed and efficiency of message handling and result in considerable reduction in operating labor. It will also provide for additional circuit capacity.

This new switching system, Fig. 1, known as Plan 55-A, has been developed for the Air Force for handling military traffic. It is expected that Plan 55-A automatic switching centers will be installed to replace the present Plan 51 centers in the United States and for overseas use, as soon as equipment is available.

To meet the needs of the U. S. Air Force for rapid and secure transmission of very large volumes of military traffic over a world-wide network, a switching system should meet requirements as follows:

1. It should provide for rapid automatic switching of messages through any number of switching centers without operating attention.

2. Where defects in a message or trouble conditions prevent automatic switching, means should be available for immediate manual (push-button) switching of messages to avoid delay.

3. The switching system must be compatible in operation with the equipment used by the other military services, so that messages may be relayed from one service to another without manual retyping. Obviously, the switching system must also be compatible with any other message-relaying system in use by the Air Force.

4. The switching equipment must be capable of either automatically or manually switching multiple-address messages.

5. The equipment should be designed on the "building block" principle, with the minimum number of different types of cabinets, each complete in itself, with plug-in connections to the other cabinets arranged for quick installation, or quick removal and reinstallation at another location of all or part of a switching center as may be required. No equipment that is essential for switching should be used in common by the entire switching center.

6. Fast handling of all traffic is essential, with preference in switching being given to messages of high precedence.

The Plan 55-A switching system, developed by Western Union to meet these requirements, consists of groups of equipment units installed in switching centers interconnected over a network of lines or radio channels to form an operating system for automatically relaying telegraph messages. A typical Plan 55-A network, such as that shown in Fig. 2, has a number of reperforator switching centers interconnected by trunk lines, with lines radiating from each center to tributary stations in the area served by that center. Messages originated at any tributary station are relayed automatically through one or more switching centers to their destina-

Paper 58-45, recommended by the AIEE Telegraph Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2-7, 1958. Manuscript submitted October 14, 1957; made available for printing November 15, 1957.

G. S. VERNAM is with The Western Union Telegraph Company, New York, N. Y.

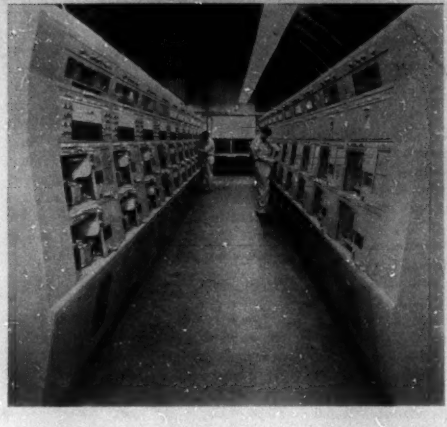

Fig. 3. Sequence number indicator

Fig. 1 (left). Plan 55-A prototype set up for test

tions at other tributary stations. This system may be operated over a nationwide network of trunk lines or radio channels and may be expanded beyond national and continental boundaries. A Plan 55-A switching center can exchange traffic with switching centers using other types of switching equipment, including Plan 51 reperforator switching or semiautomatic, "torn-tape," relaying equipment.

In Plan 55-A switching centers, messages are received and retransmitted automatically in the form of perforated tape. Routing is controlled by "routing indicators" (normally groups of six letters) recorded in the tape as part of the heading of each message. The form of message

Fig. 4. Switching single-address message through two switching centers

conforms to standards agreed upon among the Armed Services, and the switching equipment has been designed to be compatible in operation with the equipment which is being used by the other military services.

Messages may be switched automatically through several switching centers without requiring the attention of operators, except at the points or origin and destination. However, each receiving position at a switching center may be converted to manual (push-button) switching, at any time, by operating an "auto-manual" switch. It is expected that automatic switching will be the normal operating method for use in all cases where the quality of reception at the switching center and of tape preparation at the point of origin permits. However, in case of failure to switch automatically, because of incorrect routing indicators, or other errors in the received message tape, a supervisory signal is operated to call in a switching attendant so that the message may be manually switched without delay. It is also contemplated that small centers might be set up quickly in an emergency, with the automatic switching equipment omitted to save time in installation.

Message Security

Numerous safeguards and alarms are provided throughout the system to prevent errors, avoid delays, and guard against lost messages. Each message is numbered in sequence as transmitted to an outgoing line or channel and these channel numbers are automatically checked as the messages are relayed. For this purpose, automatic message-numbering machines are provided to transmit the office call, channel designation, and serial number ahead of each message. For each incoming circuit a number comparator device, known as a sequence-number indicator (SNI), is provided to check these numbers automatically. The SNI is similar in design to the automatic numbering machine and is shown in Fig. 3.

It is contemplated that some messages will be transmitted in code or cipher. For this purpose either on-line or off-line automatic ciphering equipment can be used. This cryptographic equipment is not part of the Plan 55-A switching equipment, and is not discussed in detail. With on-line cryptographic equipment, mes-

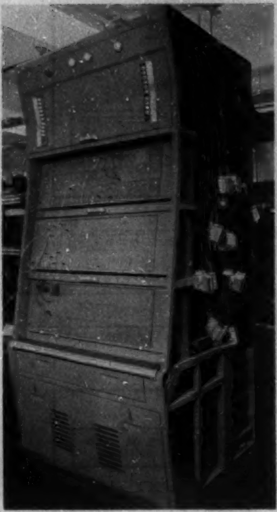

Fig. 5. Director-translator cabinet

sages are deciphered automatically as received in a switching center; they pass through the center in the clear, and are automatically enciphered again as transmitted out of the center. In such cases it is necessary to control the distributor-transmitters that send to outgoing lines, so as to maintain synchronism with the encrypting equipment. The distributor-transmitters are of a type permitting this control. With off-line cryptographic equipment, messages are enciphered at the point of origin, transmitted through the switching centers in cipher, and deciphered at the point of destination. Such messages must have clear headings for routing purposes and must avoid the chance occurrence of the message-termination character combination (normally LF NNNN) in the ciphered message text.

Message Precedence

Messages are transmitted from the office of origin in order of precedence and are delivered at their destinations in the same order. There are six precedence classifications designated in the message by repeated characters called "precedence prosigns." For switching purposes the first three precedence classifications are normally considered as "high-precedence" and the last three as "low-precedence." High-precedence messages are given preference in switching to avoid any possible delays.

Message Transit Through Switching Centers

The transmission of a single-address message from origin to destination, through two switching centers, is illustrated in Fig. 4. At each switching center the message is reperforated and transmitted twice. The first reperforation is at a receiving or incoming line position. The message is then switched and transmitted "across office" to a sending or outgoing line position where it is reperforated and transmitted again.

Message Format

The form of the message, at each stage, is shown at the bottom of the drawing. As transmitted from the office of origin and recorded by the printer-perforator at the first switching center, the start-of-message (SOM) characters ZCZC and the message serial number are followed by the precedence prosigns and routing indicator, or indicators, the text of the message and the end-of-message (EOM) characters LF NNNN.

Both automatic and manual switching are controlled by certain characters which appear at specific places in the message. An extra character (X, Y, or Z) may appear after the SOM character ZCZC. This character is used for selective control in certain cases, particularly in the case of multistation lines or way wires. Following the end of the preceding message, the first significant characters of the next message are ZCZC. Intervening characters which may have been inserted by the printer-perforator for feed-out, or by the station of origin, are treated as extraneous characters that are stepped through the transmitter and discarded.

The incoming message channel number consists of circuit-identifying letters and a 3-digit serial number. These characters are checked by the SNI, before the message is switched. Checking each received message serial number, as it appears in the tape, prevents loss of messages, facilitates identification of messages for reruns and also serves as a periodic transmission check on the line and on the operation of the transmitter and printer-perforator. In case of a wrong number comparison, transmission is stopped immediately and supervisory alarm signals are actuated. As this occurs before the message has been switched, and as transmission across office has not started, it is not necessary to send a cancellation notice.

Extraneous characters may appear in the message tape after the number. These characters may have been introduced into the tape at the point of origin, or at a torn-tape relay center, for the purpose of providing sufficient non-intelligence tape for insertion in manually operated tape relay equipment. One or more channel numbers associated with preceding transmissions may also appear at this point. All such characters are treated as extraneous information and are idled through the transmitter, which stops automatically when it reaches the LINE FEED character preceding the precedence prosign characters.

As described later, the transmitter at the receiving position is designed so that it can step through and read the precedence characters and routing indicators twice, first for switching control, and second to transmit them across office. After the first passage through the transmitter, indicated route connections are set up by switches in the receiving position, but actual cross-office line connections are not established until the EOM characters are received, except that in the case of "flash" or "emergency" messages, such connections are established immediately.

When the cross-office connection is set up, a new outgoing channel number is recorded in the tape at the sending position, transmitted from the automatic numbering machine. The incoming channel number is then transmitted across office by the SNI and the text and EOM characters are sent by the transmitter. After the EOM characters the cross-office circuit is disconnected.

From the sending position the message may be sent to a tributary of the same switching center, but in most cases the message will be switched through at least two centers. The message, as received by the printer-perforator at the second center, is the same as when it was received at the first center except that it now has two serial numbers, an outgoing channel number, and an incoming channel number. The operations involved in transmitting the message through the second center are the same as those just described for the first center, except that when the first number is checked by the SNI, the second number steps through the transmitter and is discarded. A new outgoing channel number is added at the head of the message by the numbering machine and the former outgoing channel number becomes the incoming channel number at the second center. Only two channel numbers are carried along with the message as it is relayed from center to center, thus providing adequate identification while conserving line time.

Multiple-Address Messages

Multiple-address messages are recognized as such by the presence of more than one routing indicator. Each routing indicator is preceded by a space character and the last routing indicator is followed by a carriage return character. All routing indicators are printed in one line and the number of routing indicators in a message is limited to nine. Multiple-address messages are automatically processed so as to transmit an individual copy of the message to each ultimate destination. In this process the routing indicators are segregated so that each final copy of the message contains only one routing indicator, corresponding to its destination. At a switching center several of the routing indicators in a message may require the same circuit outlet. For example, two or more routing indicators may be for tributaries of another switching center, or for more distant centers to be reached through the same intermediate switching center. Such messages are transmitted to the intermediate center containing only the routing indicators for which that center is responsible.

Any receiving position can switch a multiple-address message directly to not more than four outlets. As relatively few messages require switching to more than four circuit outlets, most messages may be switched directly from the receiving positions. All preliminary operations for a multiple-address message are the same as for a single-address message up to the point where the first routing indicator has been processed. The space character following the first routing indicator is identified and the transmitter is restarted to process the second routing indicator. This process continues until a carriage return character, after the last routing indicator, identifies the end of the routing line.

In relatively rare cases, a message may need to be switched to more than four circuit outlets. In such cases, all routing indicators requiring an outlet different from the first three, are sent with a copy of the message to an extra operating position assigned for this purpose. The messages as recorded at this extra position contain at least three fewer routing indicators than appeared in the original message. In very rare cases a message with eight or nine routing indicators may need to be transmitted to an extra position a second time.

Switching Center Components

The two principal items of equipment required in a Plan 55-A switching center are the incoming and outgoing line consoles or cabinets. Each cabinet houses two operating positions. The incoming line cabinet has a control cabinet installed behind it to provide additional mounting space for equipment. These cabinets are interconnected by cables terminated in multiconductor plugs and sockets. To meet military requirements, all cabinets of each type are alike and require no essential common equipment to set up an operable center for manual switching. The incoming and outgoing cabinets are linked together by cross-office switching circuits over which messages are transmitted electronically at 200 WPM (words per minute). In Fig. 1, the incoming or receiving cabinets are at the left and the outgoing or sending cabinets at the right side of the aisle.

These cabinets contain all the equipment needed for reperforating, transmitting, and push-button switching. The building-block principle thus obtained enables a center to be expanded or contracted as circumstances dictate with the minimum of disturbance to traffic handling. As initially equipped, each incoming line position can switch messages to a maximum of 200 circuits and 100 destinations, by providing a suitable number of outgoing line consoles. By adding switches, the equipment can be expanded to 400 circuits and 200 destinations.

A third type of equipment, a director-translator cabinet, shown in Fig. 5, is required for automatic switching. The cabinet houses two directors and a translator. It is similar in design to the receiving cabinets and is normally installed at the end of a receiving row. The director receives routing information from the message tape and it controls switching operations at the start of each message. The translator receives routing indicators from the director and translates them into switch settings. As these operations take only a few seconds, a relatively few directors and translators are required. It is proposed to install them in the ratio of one director cabinet for every 25 incoming line cabinets.

The cabinets of all three types are 84 inches high, 38 inches wide and 33 inches deep. Associated with each receiving or incoming line cabinet is a receiving control cabinet, shown at the left in Fig. 6, which contains rotary switches and other control equipment. The control cabinet is installed directly behind its associated receiving cabinet, with a maintenance aisle between. To conserve floor space, the control cabinets may be installed against a wall or another row of cabinets. A similar arrangement is used for the director cabinet, with two directors housed in the rear cabinet and a translator and associated connecting relays in the front cabinet.

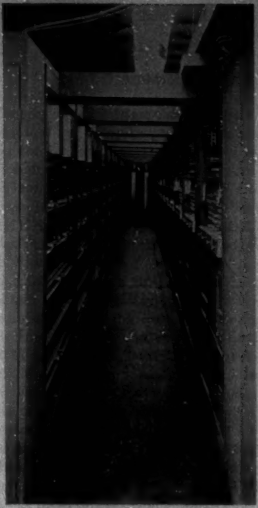

Fig. 6. Maintenance aisle behind receiving cabinets

In addition to the three types of cabinets just described, certain common equipment, is normally provided at a "traffic control center." Although a switching center may be operated without this common equipment, it is desirable to provide it to facilitate traffic handling and supervision. This equipment includes a connection indicator board, a traffic-routing board, a close-out indicator board, and supervisory printer sets, to be described later.

Receiving Positions

Each incoming line cabinet contains equipment for two receiving positions. Either position may be used to terminate an incoming trunk or single-station tributary circuit. The upper position may be used also to terminate a multistation circuit or to terminate a trunk having separate high- and low-precedence number sequences.

Printer-Perforators

Each receiving position is equipped with type 28 printer-perforator for reproducing incoming messages in printed-perforated form; see Fig. 7. Associated circuits designed to detect and count bell signals (upper case S), the SOM signal ZCZC and the EOM signal LF NNNN. The bell signals are used to detect "flash" and "emergency" messages. The EOM signal controls the message-waiting indicator (MWI), adding one on its dial for each message received. The transmitter circuit subtracts one for each complete message transmitted, so that the MWI dial indicates the number of complete messages on hand that have not been completely transmitted. The MWI also controls tape metering and is so arranged that blank tape will be fed out if incoming reception stops after the EOM, if the MWI indicates not more than one message on hand. The SOM and EOM signals are received alternately, as they occur at the start and end of each message. If the EOM signal is missing or defective, as received, there will be two successive SOM signals. This disables the MWI ADD circuit and operates a no-EOM alarm, when the MWI pointer restores to zero. This action blocks cross-office transmission, thus preventing a message from following through to the same destination after a preceding message with a defective EOM combination. The operating attendant restores service by restarting the transmitter, stopping it again at the end of the message and then operating an XMIT EOM switch to initiate automatic transmission of a correct EOM signal.

Loop-Gate Transmitters

Each receiving position has a loop-gate transmitter, shown in Fig. 8, for reading characters in the message tape and transmitting them at 200 WPM to the automatic switching director or across office to a reperforator at a sending position. Associated with the transmitter is a SNI for checking incoming message numbers, as recorded in the tape, and retransmitting them across office at the proper time. The transmitter also has associated electronic means for detecting certain characters in the tape as they pass through the transmitter. A motor-driven tape winder is provided to store message tape after transmission. An electronic transmitter is also provided to transmit messages and to transmit and receive control signals across office.

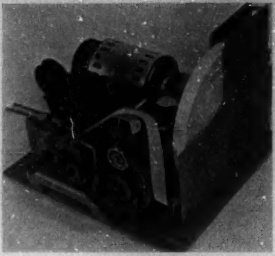

Fig. 7. Type 28 printer-perforator for incoming messages

The loop gate is a slidable latch which holds down the tape and permits sending certain portions of the message twice. With the loop gate in its right-hand position the transmitter functions, in the same way as any conventional magnet-stepped transmitter, to idle blank tape through, past the sensing pins. The SOM characters ZCZC start the SNI which checks the call letters and message number in the tape. If the message number is incorrect, the transmitter stops and a wrong-comparison signal lights to call an attendant who will take necessary corrective action. If the message number is correct, the transmitter steps the tape ahead until it detects a line feed (LF) character, thus stepping through and deleting any extra numbers or other extraneous characters that may appear in the tape at this point. Upon detecting the line feed, the loop gate on the transmitter slides to the left, holding the tape so that it cannot pass completely through the transmitter, but can step past the sensing pins forming a loop above the transmitter. Characters fed into this loop may be transmitted a second time.

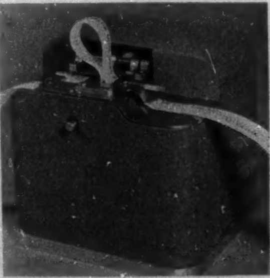

Fig. 8. Loop-gate transmitter for sending messages across office

Automatic Switching

For automatic switching, with the loop gate at the left, a connection is obtained to a director and the precedence prosign characters and the routing indicator or indicators are transmitted to the director, which returns switching information to the receiving position, for setting up the cross-office connection to the desired destination. The loop gate then returns to its right-hand position, placing the original character (the first character after the line feed) over the sensing pins. The transmitter is now ready to transmit the message across office at the proper time.

Manual Switching

For manual switching, when the loop gate slides to the left, a message-waiting (MSG WTG) lamp lights to call the attendant, who looks at the precedence prosign characters on the tape and depresses a high- or low-precedence push-button, which associates the transmitter with the push-button panel, advances the prosign characters through the transmitter, extinguishes the MSG WTG lamp and lights a "switching control" lamp. The attendant now depresses a panel push-button for each routing indicator and then a START push-button to complete the manual switching operations.

Electronic Cross-Office Transmission

Electronic methods are used for transmitting signals across office over a single conductor. The electronic transmitting and receiving equipments are synchronized to the 60-cycle power supply. The message characters are transmitted at 200 WPM (20 characters per second), which is equivalent to one character for every third cycle of the 60-cycle power supply. Certain control pulses are transmitted over the same cross-office line conductor, in either direction, at the rate of 60 pulses per second. As compared to other switching systems, the use of a single conductor, in this system, greatly reduces the number of cable conductors, multiconductor plugs, sockets, and switches required. For example, eight levels of a single 25-point rotary switch serve to select any one of 200 sending positions.

The electronic units consist essentially of a pulse generator, common to the two operating positions in each cabinet, an electronic transmitter for each receiving position and an electronic receiver for each sending position. These units generate, transmit, and detect the message and control pulses that are sent across office and, in addition, step the tape transmitter and numbering machine, detect and indicate trouble conditions, read certain message characters as they are being transmitted at high speed, test the idle or busy condition of selected routes, and control the operation of other equipment, such as the SNIs, the MSG WTG indicators, and the automatic switching directors. The pulse generator and electronic transmitters are shown at the top of Fig. 9.

Sending Position Cabinets

Each outgoing line cabinet contains equipment for two sending positions. The upper position may be used to terminate any type of outgoing line, including a multipoint circuit (way wire). The lower position can terminate any line except a multipoint circuit. Either position may be used as part of a multichannel group.

Sending Positions

Each sending position is equipped with a Type 28 multimagnet reperforator, shown in Fig. 10, for reproducing messages received over cross-office circuits in perforated (not printed) tape form. This reperforator is associated with an electronic receiver which operates on signals received across office at 200 WPM as sent from an electronic transmitter associated with the loop-gate transmitter at a receiving position. The reperforator also receives signals from an automatic message numbering machine at the same sending position. In the case of multipoint circuits, terminated at upper sending positions, there may be two or three numbering machines (one for each way station), any one of which can send into the reperforator.

When a cross-office connection is established, the numbering machine automatically sends, into the reperforator, the SOM characters ZCZC, a multistation selector code character (X, Y, or Z) if required, the station and channel designation letters, and the message number. This number is followed by the incoming channel number transmitted from the SNI at the receiving position. The latter number is always preceded by the characters ZC and followed by CR CR LF. The message is then transmitted across office by the loop-gate transmitter, first the precedence prosign characters and routing indicators from the tape loop and then the remainder of the message, including the EOM characters LF NNNN. At this point, the loop-gate transmitter stops, the numbering machine sends two blanks into the reperforator, and the cross-office circuit is released.

Character Checking

The reperforator is equipped with read-back contacts operated by an extra set of sensing pins located five characters to the left of the punch pins. These pins read certain character groups in each message to verify the correct operation of all equipment involved in cross-office transmission. The SOM characters ZCZC from the numbering machine are the first characters checked. The appearance of this combination indicates that the local equipment of the sending position is operating properly, including the numbering machine and the reperforator. The ZC characters ahead of the incoming channel number verify the operation of the SNI and cross-office transmission. At the end of the message, when two blanks are transmitted by the numbering machines after the EOM characters, the line feed and first N are fed over the read-back pins and checked, thus verifying that the reperforator is still operating properly at the end of the message. The cross-office connection is then released.

The ZC characters must check to start cross-office transmission of the message. Failure to check prevents transmission, locks out the sending position, and operates an alarm signal at the sending position and a reswitch signal at the receiving position. A number-cancellation notice is then transmitted automatically from the receiving position. The sending position remains out of service until manually restored after the trouble is cleared. At the receiving position an attendant sets the tape back to the start of the message and releases it to be reswitched. It will be automatically switched to the same destination through another sending position, if one is available, or to an intercept position for storage until the original sending position is restored to service.

If the LF N combination at the end of the message fails to check, the sending position alarm signal is operated as described and the switch-to-supervisor signal is lighted at the receiving position. In this case the attendant at the receiving position sets the tape back to the start of the message and switches it manually to the supervisor, who resends it designated as a "suspected duplicate," as a complete or nearly complete message may have been transmitted before the trouble occurred. The attendant at the sending position operates a transmit-cancellation-notice switch to cancel any partial message that may have been recorded in the tape at that position.

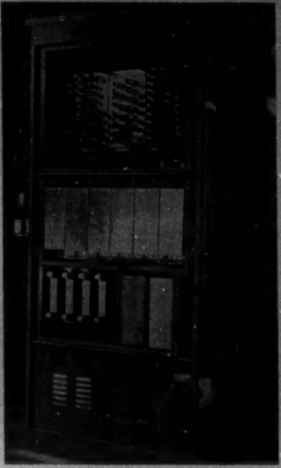

Fig. 9. Receiving cabinet, rear view, with electronic units at top

Multichannel Destinations

To handle heavy traffic loads to a particular destination, several outgoing line circuits and sending positions may be required. All sending positions in such a multichannel group represent the same destination. Any message for that destination may be switched to any sending position in the group that is available for use at the moment. The selection of a particular position is controlled by a load-distributor circuit. This circuit gives first choice to any sending position that has a tight tape condition, since such positions have no other messages on hand for outgoing transmission. During busy periods, when no position in the group has tight tape, each sending position in the group is selected in rotation as cross-office connections are established, so that the traffic is evenly divided among the channels.

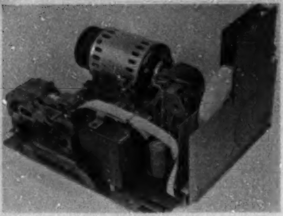

Fig. 10. Type 28 reperforator for receiving across office

Transmitter-Distributor

Each sending position is equipped with a Type 28 multicontact transmitter-distributor, shown in Fig. 11, for transmitting, to the outgoing line, the messages that the reperforator has recorded in perforated tape form. The transmitter-distributor operates at 60 or 100 WPM. It has two cam shafts; one, a transmitter shaft that drives mechanisms for feeding the tape and sensing the perforations, and the other a distributor shaft for sending character signals to the line in start-stop code. The shafts can operate together or separately, so that blank tape or other characters may be idled through the transmitter without sending to line and special character signals, controlled by a rotary switch, may be sent to line by the distributor contacts without stepping the tape through the transmitter.

When a message is received across office, slack tape allows the transmitter-distributor to start. At first, any blank tape is idled through the transmitter, with the distributor stopped, so that the blank characters are not sent to line. When the first character in the tape that is not a blank reaches the transmitter sensing pins, the transmitter shaft stops and the distributor seizes a connection to line; then both shafts operate to send the message to line. When the sensing contacts detect the EOM combination LF NNNN, both shafts stop and the line connection is released. These operations are repeated as each message is transmitted to the outgoing line.

Two-Position Outgoing Line Termination

Two sending positions may be arranged to send alternately to the same outgoing line circuit. Normally one position is used for high-precedence traffic and the other for low-precedence traffic. The transmitter-distributor of the low-precedence position releases the line at the end of each outgoing message to allow the high-precedence position to cut in, if it has a message to send. When this occurs, all high-precedence messages on hand are transmitted to line before the low-precedence position can seize the line again. This arrangement makes it possible to send a high-precedence message to line ahead of previously stored low-precedence messages. If the line is part of a multichannel group, the low-precedence position may be so arranged that it will accept and store not more than one message during periods when the high-precedence position is sending to the outgoing line. This is to avoid accumulating any considerable number of messages at the low-precedence position during periods when it cannot send to line.

Added EOM Characters

When an outgoing line is used as a trunk to certain other types of switching centers or to a multistation circuit (way wire), it may be necessary, for the proper operation of the other switching center or way station, to send certain added characters after the normal EOM. These added characters are controlled by setting a switch located inside the console. This switch has five positions as follows:

Position	Added EOM Characters	Purpose
1	none	sending to plan-55 centers or tributaries
2	5 blanks	sending to U.S. Army automatic switching centers
3	3 carriage returns 2 letter shifts	sending to Plan-51 centers
4	10 letter shifts	sending to torn-tape stations or centers
5	blanks, pauses	disconnecting a way station

Multistation Circuits: Way Wires

Multistation circuits extend from a switching center to two or three tributary stations. These circuits are operated duplex. Each station is equipped for selective control so that each message transmitted from the switching center is recorded only at the station to which it is directed. A selecting letter (X, Y or Z) is assigned to each station. This letter is transmitted by an automatic numbering machine immediately after the SOM characters ZCZC, and is recorded in the tape ahead of the message serial number. The upper sending positions are arranged to mount two or three numbering machines for this purpose, and to maintain an individual message number sequence with each station. As it passes through the transmitter-distributor, the selecting letter, in the tape, selects the proper calling signal so as to cut in the printer at the particular station that is to record the message. The printers at the other stations are locked out until the end of the message.

Fig. 11. Type 28 transmitter-distributor for sending to line

At each way station, messages are prepared in perforated tape form for transmission to the switching center. Only one station can send at a time. Each way station uses its own sequence numbers for transmitted messages. These numbers are checked automatically at the switching center by SNIs individual to each station. The SNIs are selected by selecting letters similar to those used for outgoing messages. The upper receiving positions in the incoming line cabinets are arranged to mount the additional SNIs. Depressing either a high-precedence or a low-precedence push button at a tributary station indicates, at the switching center, that a message is ready for transmission from a way station. The switching center equipment determines whether a high-precedence message is indicated and, if so, invites each station in turn with a high-precedence message to send, automatically accepting high-precedence messages as long as any are indicated. If there are none low-precedence messages are accepted in a similar manner. To give all stations an equal opportunity to send messages within the same precedence group, the invitation sequence always starts with the station following the one that has just previously transmitted a message.

Advantages of High-Speed Cross-Office Transmission

Messages are received over incoming lines at 60 or 100 WPM, are transmitted across office at 200 WPM and are then retransmitted to outgoing lines at 60 or 100 WPM. With the cross-office speed at least twice the speed of transmission to outgoing lines, enough messages may be sent across office to any sending position to keep the outgoing line busy, while the cross-office side of that position is idle at least half of the time. It is obvious therefore that the receiving positions will usually obtain an immediate cross-office connection and no appreciable amount of unsent tape should accumulate at these positions. If an occasional busy condition should cause an accumulation, however, the differential between the high cross-office speed and the lower incoming line speed would transmit messages away from the receiving positions at least twice as fast as they are being received, thus rapidly reducing the tape accumulation. The line circuits may thus be operated at a very high utilization level, without causing appreciable traffic delay. The transmitter-distributor at a line-sending position automatically functions to send continuously as long as there is any traffic at the sending position to send. Therefore the cross-office line need operate only intermittently to provide a full outgoing circuit load.

Switching to Busy Destinations

If a receiving position has a single-address message to be switched to an outgoing circuit that is busy, the message waits until a circuit to the desired destination becomes available. If the wait is unduly long, or if the message is a flash or emergency message, an alarm will operate to call an attendant to the position to take suitable action, such as interrupting a less important message or switching the message over an alternate route.

In the case of a multiple-address message, cross-office connections to the desired destinations are established one at a time. After a connection is established to the first available destination, any additional required connection that is delayed by a busy condition is diverted automatically to an intercept position after a timed interval of about 30 seconds. This is a standard sending position which has its outgoing line connected as an incoming line to an intercept receiving position, at which a copy of the message is stored and retransmitted to the required destination when a circuit becomes available.

When the required cross-office connections have been established, the numbering machine associated with each sending position selected transmits the next consecutive channel number for its circuit outlet. The SOM characters ZCZC are checked at each sending position and, if correct, the receiving position sends the incoming message number from the SNI and the precedence prosign characters from the tape to all connected sending positions. The routing indicators are then transmitted, sending each routing indicator to only one sending position, as required. The end-of-routing characters (CR CR LF D) are then broadcast to all connected sending positions, followed by the remainder of the message and the EOM characters LF NNNN. The cross-office circuits are then released.

If the ZC characters fail to check correctly at any of the connected sending positions, the message is not transmitted across office, but instead a number-cancellation notice is transmitted and the cross-office lines are released. As in the case of a single-address message, alarms are operated at the sending position in trouble and at the receiving position. An attendant called to the receiving position reswitches the message. If the EOM characters fail to check correctly, the message is resent as a suspected duplicate. Two copies of the message may be received at some destinations, but one will be designated "suspected duplicate."

Traffic Control Center

Although a switching center could be operated without a traffic control center, this equipment is normally provided, as it facilitates traffic handling and supervision. The traffic control center equipment includes a connection indicator board, a traffic routing board, a close-out indicator board, and receiving and sending printer sets.

Connection Indicator Board

The connection indicator board has a neon signal lamp and a push button for every receiving and sending position. It provides means for readily determining which sending and receiving positions are connected over cross-office lines at any time. Operating a push button on the board associated with any operating position lights the neon lamp for any operating position with which it is connected. This information is useful for maintenance purposes and also for certain operating conditions. For example, assume that a flash or emergency message has been received at a receiving position, and switched across office to some sending position. Such messages include bell signals which call an attendant to the receiving position. The attendant notifies a supervisor at the traffic control center that such a message is being transmitted from a particular receiving position. The supervisor depresses the push button corresponding to this position and ascertains the sending position to which it is connected. The supervisor then sends an attendant to that position to ensure that the message is not delayed by equipment or line trouble or by a large accumulation of message tape previously switched.

Traffic-Routing Board

The traffic-routing board is a jack board for making temporary changes in the routing of messages by the use of patching cords. Two pairs of jacks marked FROM and TO are provided for each destination to which this switching center is connected. One pair of jacks is for high-precedence traffic and the other for low-precedence traffic. Changes in routing are made by patching the FROM jack of one destination to the TO jack of another, thus diverting traffic from the first to the second destination. High- and low-precedence traffic may be independently routed. For example, if a trunk route between two switching centers becomes overloaded with traffic, or otherwise unusable, the high-precedence traffic or all traffic may be temporarily sent over an alternate route through a third switching center. By patching only the high-precedence jacks, high-precedence traffic for stations that are closed at night may be diverted to a separate position for commercial refile, while, at the sending position by simply stopping the transmitter, the low-precedence traffic is allowed to accumulate for later transmission when the station reopens.

Close-Out Indicator Board

The close-out indicator board contains groups of signal lamps to indicate the operating status of the sending line positions for the information of the supervisory personnel. These signals show which sending positions are closed out on the cross-office side or have their transmitters stopped for any reason.

Relay-Scanning-Design Technique Generates High Accuracy and Speed in Analog-to-Digital Transducer Measurements

ANDREW F. KAY
ASSOCIATE MEMBER AIEE

AN accelerated program of flight-testing an aircraft or its power unit it often instrumental in more speedy development of its final design for quantity production. The time rate at which flight-tests can be carried out is rarely dependent on a time-in-the-air factor, but instead hinges on the time required for calculating and computing the data resulting from individual tests. Tremendous amounts of data from many different sources must be reduced and correlated to permit equipment modifications before subsequent tests can take place. When data reduction of analog-type information to be used for computer calculations is performed by manual devices or human beings, the time between individual flight tests often spans a period of days, or even weeks. This does not take into account the increased chance for inaccuracies to occur and the extremely high cost of this type of data-reduction process.[1]

Simplified Data Reduction

Time and cost factors have stimulated a considerable amount of development in the area of analog-to-digital converters for data recording during the past few years. With these instruments, data can be taken directly from the source, converted to digital readout form, and recorded by various means such as punched or magnetic tape or telemeter directly to remotely located recorders. These digital recordings can be played back later in computer instruments without the need for further data reduction or conversion. By such means, final data computations are performed literally in a few hours so that subsequent flight tests can take place with a much shorter time interval. Thus a speedy day-after-day series of flight tests can greatly decrease aircraft or engine development time.

The problem of taking multiple transducer measurements becomes extremely difficult when the number of data-sensing elements increases. Great numbers of these sensing units require a data-recording system capable of handling a complete series of readings within a certain time cycle. In this case, data-recording-equipment size presents the greatest difficulty, particularly in aircraft applications. In addition to having data-reduction problems, analog recording equipment becomes extremely bulky when a large number of readings are necessary. Completely electronic digital recording devices, on the other hand, are extremely complex and large as well as being difficult to maintain because of adverse environmental conditions. With the factors of size, complexity, and ruggedness in mind, it was determined that a simplified relay scanning system of less than 1,000 cubic inches could be devised to function more effectively in high-accuracy digital reading of transducer measurements.

Discussion

RELAY SCANNING ANALOG-TO-DIGITAL CONVERTER

Some of the most recent techniques in analog-to-digital converter design include electromechanical high-speed scanning relays, chopper comparators, and elimination of preamplifiers. In operation, a system developed by Non-Linear Systems, Inc., which utilizes all of these techniques, Figs. 1 and 2, converts low-level d-c input signal voltages over a range of 20 microvolts to 20 millivolts into three decades of binary coded decimal pulses proportional to the input voltage. Each decimal unit is equivalent to 20 microvolts of the input voltage.

Basically, this analog-to-digital converter creates an internal voltage, termed the feedback voltage, which is varied until it equals the unknown input voltage from the transducer. As the instrument scans, the internal voltage becomes equal to this input voltage and as the system balances, the converter supplies an electric serial pulse train output to indicate the transducer voltage reading in digital form.

LOW-LEVEL AMPLIFIER VERSUS PREAMPLIFIER

Rather than using a preamplifier which raises the input voltage to a higher level before comparison, it was determined that more accurate and simplified comparisons could be reached by making comparisons at the actual level of the input signal. The error voltage is then amplified in the low-level amplifier which is within a digital servo loop. In this way not only is a separate preamplifier unnecessary, but also possible drift and distortion, often encountered in preamplifiers and their feedback networks, are eliminated.

Requirements for the low-level or error amplifier are much fewer than for a preamplifier. In this type of application, preamplifier gain must be held within 0.15% or better, and requirements for stability and phase response are even more critical. By comparison, a 20 or 30% variation in error amplifier gain will not affect the final reading appreciably. By using a chopper to sample alternately the reference and unknown voltages, certain advantages are obtained which make the low-voltage-level comparison possible. Choppers are available with noise levels held below 1/10 microvolt, which suits them particularly well for their application in this system. A further advantage of the chopper is evident in the fact that through metal-to-metal contacts there is no distortion such as might result if electronic switching with vacuum tubes or transistors were used.

AMPLIFIER

The d-c amplifier contains four high-gain amplifying stages as well as a restorer stage to maintain a constant reference level in the low-level amplifier. In addition, the amplifier circuitry includes two multivibrators; one actuates the restorer through a diode gate, while the other generates 400-cycle clock pulses. Receiving a square wave input from the low-level amplifier stages, the amplifier differentiates and clips this input to form

Fig. 1. Exterior view of relay scanning analog-to-digital converter

a clipped sawtooth wave. This waveform is gated so that the clock pulse occurs coincidentally with the sawtooth trailing edge. Referred to as an anticlock pulse, the sawtooth cancels the effect which a lone clock pulse would have on a scanner unit. The scanner unit contains a bistable multivibrator which operates the high-speed scanning relay, which in turn connects and disconnects precision resistors in the reference voltage divider. Final output digits of the converter will be read in terms of the absence of pulses in the pulse train. Multivibrators in the amplifier circuit shape the clock pulses and pulse outputs for 1/800-second duration. An additional multivibrator provides reset pulses to reset all scanner units to starting position at the end of each digital readout period.

When the error voltage from the chopper switch is a positive square wave, indicating that the reference voltage is lower than the unknown voltage, the amplifier puts out an anticlock pulse. This anticlock pulse from the amplifier causes the digit being measured to readout. When the error is negative the amplifier has no output, and the clock pulse causes the scanner unit to have no readout.

CONVERTER INPUT

Since this analog-to-digital converter system utilizes a transformer input to the amplifier, it is particularly well suited to strain-gage and other transducer voltage measurements. Strain-gage transducers almost invariably require a measuring instrument which is completely isolated from ground. This factor is important in other transducers such as thermocouples which measure temperatures directly from metallic surfaces. In addition to erroneous readings, an unisolated system could create phase lags and require costly installation procedures to reduce detrimental effects. This system can be used on any measuring device which transforms any transient or quasi-static physical information into low-level direct voltages. However, the system could be easily modified to digitize high-voltage levels also. When properly programmed the input signal can be supplied by any combination of transducers as long as their outputs vary over the same voltage range. An example of this varied input might occur in an aircraft test application where, in addition to strain-gage and thermocouple readings, it is desirable to receive information from inputs of autopilot control, speed, and aircraft heading. When it is necessary to telemeter test readings to remote recorders, a serial digitized signal to the recorder is ideal since normal distortion due to communication equipment and conditions has no effect on the finally recorded reading. This is true since the digital output is in the form of discrete pulses as compared with varying amplitude signals where exact voltage levels determine the value of the reading.

SCANNING

A chopper, vibrating at 400 cycles per second, alternately samples the unknown and the internal reference voltages. To the reference voltage a divider circuit of precision resistors is utilized. Connected to the known and calibrated internal voltage source, the divider circuit consists of groups of precision resistors which are alternately scanned. Rather than acting as a conventional voltage divider which samples a portion of a known voltage by means of a potentiometer, Fig. 3, this system combines various precision resistors in parallel which are in turn series-connected to a common resistance. The voltage generated in the common resistance is then the comparison reference voltage. As more resistors are connected to the common resistance, more current flows in the common resistance to raise the voltage to be compared directly with the unknown voltage.

High-speed hermetically sealed relays, which have a life expectancy of more than a billion cycles, sequentially scan the precision resistors by switching them in and out of a divider network. Scanning or sampling these resistors at a rate of 400 per second, the converter selects the combination of these resistors which equalizes the reference to the unknown input voltage. The position of the relays when the system is balanced determines the digital output reading. Identified by

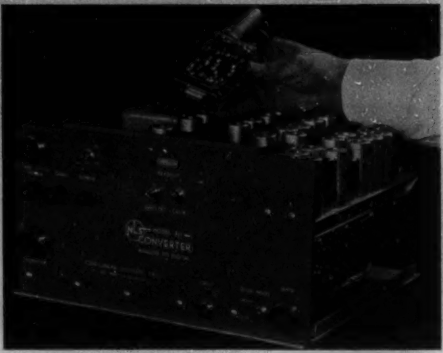

Fig. 4 (above). Scanner-unit modular construction

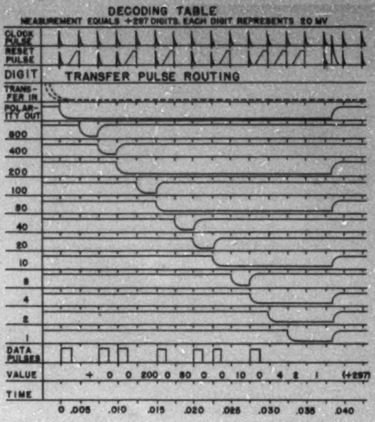

Fig. 5. Typical operational cycle of converter system

clock pulses provided by the amplifier circuit, the output is a serial train of binary coded data pulses.

The use of mechanical relays for switching the resistors during scanning is particularly advantageous when compared with electronic means such as vacuum-tube or diode devices. When the relay is open there is essentially infinite resistance between the contacts, and when it is closed there is essentially zero resistance. With electronic devices, in order to approach these optimum conditions, various complex compensating design techniques must be incorporated which add size and weight to the converter system.

Of the 13 scanner units, the first indicates polarity; the next four indicate hundreds of units; the following four, tens; and the last four are single units. Starting with the largest voltage digit, the scanner units increase the reference voltage until it equals the unknown voltage. Any time that the voltage digit or switched-in resistor makes the reference larger than the unknown, the voltage digit drops out. Each scanner unit is identical to the other 12, and is constructed as a completely interchangeable, modular, plug-in package; Fig. 4.

Operational Cycle

A typical operational cycle of this converter system is depicted in Fig. 5. Each time a clock pulse occurs, one resistor is sampled. If the increased voltage in the common resistance, which is caused by the addition of a sampled resistor, is greater than the unknown voltage, the amplifier signals the switching relay to reset the relay of this resistor. The next smallest resistor is then sampled in the same manner. Absence of a data pulse indicates that the digit is to be counted as a part of the total digital measurement. To obtain the voltage value of the digital measurement, the digits are added and their sum multiplied by 20 to obtain the reading in microvolts.

Coding

Generally, analog-to-digital converters read out in either 8-4-2-1 or 4-2-2-1 coding. Although this system can be adapted to either type of coding, the 4-2-2-1 readout was selected. With this coding, problems associated with redundancy are eliminated since the digits cannot add up to more than 9. This simplifies use of the taped output information in computers which generally incur difficulties if the decade sum is greater than 9. Decade totals with the 8-4-2-1 coding could, in some instances, be as high as 15.

Conclusions

The relay scanning analog-to-digital converter described provides one of the most favorable means for accurate and rapid recording of multiple voltage readings from low-voltage transducer sources. This system provides an optimum combination of currently available electronic and electromechanical components with respect to reliability and speed. Such innovations as mechanical divider circuit switching and elimination of preamplifier circuits have resulted in highly reliable, compact, and accurate systems for digitizing voltage measurements. The techniques described should pave the way for widespread future simplification of data reduction and computation for speedier product development in all fields of high-performance design.

Certain Applications of Matrices to Circuit Theory

LOUIS A. PIPES
MEMBER AIEE

Synopsis: This paper is intended to show the intimate relationships between the eigenvalues and eigenvectors of certain matrices and some well-known electrical parameters such as propagation constants, characteristic and iterative impedances in single-phase systems, and symmetrical components in polyphase systems whose impedance matrices have circular symmetry. The basic ideas are applied to show how Lucas functions, and the polynomials of Chebyshev and Gegenbauer enter naturally in the discussion of the propagation of potentials and currents along chains of identical and geometrically tapered quadripoles.

As IS NOW WELL-KNOWN, matrices provide a compact and flexible notation particularly useful in dealing with linear transformations, and presents an organized method for the solution of systems of linear differential equations.[1] The use of matrices in the treatment of problems in communication and electrical engineering has become increasingly popular. In recent years, it has been applied to the analysis and synthesis of 4-terminal networks[2] to the design of phase-shifting networks for oscillators,[3] to the theory of active quadripoles that include vacuum tubes as elements,[4] and to the analysis of polyphase power systems.[5]

The purpose of this paper is to emphasize that such well-known electrical parameters as propagation constants, characteristic and iterative impedances, and symmetrical components are intimately related to the eigenvalues and eigenvectors of certain square matrices.[6] The natural manner in which Lucas functions and the polynomials of Chebyshev and Gegenbauer arise in the analysis of chains of passive quadripoles is also demonstrated.

Transmission Matrix of Linear, Passive Quadripole

Consider the linear, passive quadripole or 4-terminal network of Fig. 1, which shows the general conventions of the directions usually adopted for the input and output potentials and currents. The 4-terminal network will be supposed to be an n-mesh network that has two accessible terminals as shown. The restrictions on the component elements of the internal structure of the network are that they be linear and constant. It is further assumed that the network is passive, i.e., the only sources of electromotive force are E_1 and E_2 produced by external agencies. As is well-known, the following linear relations exist between the complex potentials E_1, E_2, and the complex currents I_1, I_2 indicated in Fig. 1.[6]

$$E_1 = AE_2 + BI_2$$
$$I_1 = CE_2 + DI_2 \qquad (1)$$

The coefficients A, B, C, D are called the general 4-terminal network parameters in the electric circuit literature. It may be seen that, as a consequence of equation 1, A and D are dimensionless transfer ratios, the parameter B has the dimension of an impedance, and C the dimension of an admittance. If the elements of the internal structure of the quadripole are purely reactive, then the parameters A and D are real numbers and B and C are imaginary numbers. It may be shown that as a consequence of the reciprocity theorem,[6] the following relation exists between the four network parameters.

$$AD - BC = 1 \qquad (2)$$

To make the writing of subsequent equations more compact, it is convenient to introduce the column matrices or vectors x_1 and x_2 and the square matrix $[T]$ defined by the equations

$$\mathbf{x}_1 = \begin{bmatrix} E_1 \\ I_1 \end{bmatrix}, \; \mathbf{x}_2 = \begin{bmatrix} E_2 \\ I_2 \end{bmatrix}, \; [T] = \begin{bmatrix} A & B \\ C & D \end{bmatrix} \qquad (3)$$

With this notation, equation 1 and equation 2 may be written in the form

$$\mathbf{x}_1 = [T]\mathbf{x}_2 \qquad (4)$$

and

$$\det[T] = (AD - BC) = 1 \qquad (5)$$

where det = determinant.

The square matrix $[T]$ has been called the transmission matrix of the quadripole in the older literature of 4-terminal circuits. In certain recent papers, however, $[T]$ has been called the "chain matrix" of the quadripole.[7] Equation 4 expresses the fact that the two vectors $\mathbf{x}_1$ and $\mathbf{x}_2$ are related to each other by a linear transformation. The relations between the four quantities E_1, I_1, E_2, I_2 given by equation 1 may be expressed in the following alternative ways:

$$\begin{bmatrix} E_2 \\ I_2 \end{bmatrix} = [T]^{-1} \begin{bmatrix} E_1 \\ I_1 \end{bmatrix}, \; [T]^{-1} = \begin{bmatrix} D & -B \\ -C & A \end{bmatrix} \qquad (6)$$

$$\begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = [Y] \begin{bmatrix} E_1 \\ E_2 \end{bmatrix}, \; [Y] = \begin{bmatrix} D/B & -1/B \\ 1/B & -A/B \end{bmatrix} \qquad (7)$$

$$\begin{bmatrix} E_1 \\ E_2 \end{bmatrix} = [Z] \begin{bmatrix} I_1 \\ I_2 \end{bmatrix}, \; [Z] = \begin{bmatrix} A/C & -1/C \\ 1/C & -D/C \end{bmatrix} \qquad (8)$$

$$\begin{bmatrix} I_1 \\ E_2 \end{bmatrix} = [g] \begin{bmatrix} E_1 \\ I_2 \end{bmatrix}, \; [g] = \begin{bmatrix} C/A & 1/A \\ 1/A & -B/A \end{bmatrix} \qquad (9)$$

$$\begin{bmatrix} E_1 \\ I_2 \end{bmatrix} = [h] \begin{bmatrix} I_1 \\ E_2 \end{bmatrix}, \; [h] = \begin{bmatrix} B/D & 1/D \\ 1/D & -C/D \end{bmatrix} \qquad (10)$$

In equation 7 and 8, the matrices $[Z]$ and $[Y]$ are defined to conform to the current and potential directions adopted in Fig. 1 and as a consequence of this, $[Z]$ and $[Y]$ are not symmetric matrices. The following relations between these square matrices are easily shown to exist.

$$[Z] = [Y]^{-1}, \quad \det[Z] = -B/C, \quad \det[Y] = -C/B \qquad (11)$$

$$[g] = [h]^{-1}, \quad \det[g] = -D/A, \quad \det[h] = -A/D \qquad (12)$$

The transmission or chain matrices of the more fundamental structures that occur in the theory of communication networks are given in Table I.

Eigenvalues and Eigenvectors of Transmission Matrix

Since the input and output quantities of the general quadripole of Fig. 1 are related to each other by the linear transformation equation 4, it is instructive to determine the eigenvalues and eigenvectors of the transmission or chain matrix $[T]$.[8] To determine these fundamental quantities, consider the linear transformation obtained by placing $\mathbf{x}_1 =$

Paper 58-52, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2-7, 1958. Manuscript submitted October 21, 1957; made available for printing November 7, 1957.

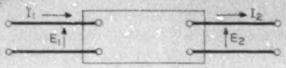

Fig. 1. Passive quadripole

x and $\mathbf{x}_2=\mu\mathbf{x}$ in equation 4. These substitutions give

$$[T]\mathbf{x}=\mu\mathbf{x} \qquad (13)$$

Let **x** have the elements x_1 and x_2, then equation 13 is equivalent to the two scalar equations

$$(A-\mu)x_1+Bx_2=0$$

$$Cx_1+(D-\mu)x_2=0 \qquad (14)$$

These two simultaneous equations give the following ratios:

$$x_1/x_2=B/(\mu-A)=(\mu-D)/C \qquad (15)$$

It may be seen that, as a consequence of equation 15, the parameter μ must satisfy the equation

$$\mu^2-\mu(A+D)+(AD-BC)=0 \qquad (16)$$

Since $\det[T]=(AD-BC)=1$, this equation reduces to the simpler form

$$\mu^2-\mu(A+D)+1=0 \qquad (17)$$

Equation 17 is the characteristic equation of the transmission matrix $[T]$.

Let $b=(A+D)/2=\text{trace}[T]/2$, where $\text{trace}[T]$ is defined as the sum of the principal diagonal elements of $[T]$. It is easy to show that the two roots of the characteristic equation 17 are given by

$$\mu_1=b+(b^2-1)^{1/2}$$

$$\mu_2=b-(b^2-1)^{1/2} \qquad (18)$$

The two roots μ_1 and μ_2 are the eigenvalues of the transmission matrix $[T]$. The eigenvalues have the property that

$$\mu_1\mu_2=1,\ (\mu_1+\mu_2)=2b=\text{trace}[T]=(A+D) \qquad (19)$$

Let

$$\mu_1=\epsilon^{a},\ \mu_2=\epsilon^{-a} \qquad (20)$$

then

$$(\mu_1+\mu_2)/2=(\epsilon^{a}+\epsilon^{-a})/2$$
$$=\cosh(a)=\text{trace}[T]/2=b \qquad (21)$$

The quantity

$$a=\cosh^{-1}(b)=1n(\mu_1) \qquad (22)$$

is recognized as the propagation constant of the quadripole.

It is noticed that if the eigenvalues μ_1 and μ_2 of the transmission matrix $[T]$ are distinct, and if $\mu=\mu_1$ and $\mu=\mu_2$ are substituted into equation 15, this determines two distinct ratios of x_1/x_2. These two ratios are the two eigenvectors of $[T]$. The two eigenvectors of $[T]$ are therefore

$$Z_1=(x_1/x_2)_{\mu=\mu_1}=(\mu_1-D)/C=\frac{(A-D)}{2C}+\frac{(b^2-1)^{1/2}}{C} \qquad (23)$$

$$=(A-D)/2C+\sinh(a)/C$$

$$Z_2=(x_1/x_2)_{\mu=\mu_2}=(\mu_2-D)/C=\frac{(A-D)}{2C}-\frac{(b^2-1)^{1/2}}{C} \qquad (24)$$

$$=(A-D)/2C-\sinh(a)/C$$

The quantities Z_1 and Z_2 are recognized to be the characteristic impedances of the transmission matrix $[T]$ are the characteristic impedances of the quadripole whose transmission or chain matrix is $[T]$. The iterative impedances of the quadripole are given by

$$Z_{1i}=\frac{\sinh(a)}{C}+\frac{(A-D)}{2C},\ Z_{2i}=\frac{\sinh(a)}{C}-\frac{(A-D)}{2C} \qquad (25)$$

From this it is seen that

$$Z_{1i}=Z_1 \text{ and } Z_{2i}=-Z_2 \qquad (26)$$

If the quadripole is symmetric, $A=D$ and relations 25 and 26 reduce to

$$Z_{1i}=Z_{2i}=Z_1=-Z_2=\frac{\sinh(a)}{C}$$
$$=(B/C)^{1/2}=Z_0 \qquad (27)$$

Powers of Transmission Matrix [T]

Since the over-all transmission matrix $[T]_n$ of a cascade of n identical quadripoles, each one of which has a transmission matrix $[T]$, is given[6] by

$$[T]_n=[T]^n \qquad (28)$$

it is convenient to develop a compact expression for integral powers of the transmission matrix $[T]$. The most fundamental manner of obtaining this desired expression is to make use of equation 13. If $\mathbf{x}_1$ and $\mathbf{x}_2$ be the eigenvectors that correspond to the eigenvalues μ_1 and μ_2, two equations are obtained of the form of equation 13:

$$[T]\mathbf{x}_1=\mu_1\mathbf{x}_1,\ [T]\mathbf{x}_2=\mu_2\mathbf{x}_2 \qquad (29)$$

If it is realized that only the ratios of the elements of the eigenvectors are specified by equation 15, the following may be written:

$$\mathbf{x}_1=\begin{bmatrix} Z_1 \\ 1 \end{bmatrix},\ \mathbf{x}_2=\begin{bmatrix} Z_2 \\ 1 \end{bmatrix} \qquad (30)$$

The square matrix

$$[M]=\begin{bmatrix} Z_1 & Z_2 \\ 1 & 1 \end{bmatrix} \qquad (31)$$

constructed by taking $\mathbf{x}_1$ and $\mathbf{x}_2$ as columns is the model matrix of $[T]$. In terms of the modal matrix, the two equations 29 may be combined into the single equation

$$[T][M]=[M]\begin{bmatrix} \mu_1 & 0 \\ 0 & \mu_2 \end{bmatrix}=[M][d] \qquad (32)$$

where $[d]$ is the diagonal matrix whose elements are the eigenvalues μ_1 and μ_2. This matrix has the following properties:

$$[d]^n=\begin{bmatrix} \mu_1^n & 0 \\ 0 & \mu_2^n \end{bmatrix},\ \text{trace}\,[d]=(\mu_1+\mu_2)$$
$$=2\cosh(a) \qquad (33)$$

If (4.5) is postmultiplied by $[M]^{-1}$, the result is

$$[T]=[M][d][M]^{-1} \qquad (34)$$

If equation 34 is multiplied by itself n times, the result is

$$[T]^n=[M][d]^n[M]^{-1} \qquad (35)$$

The inverse of the modal matrix $[M]$ is

$$[M]^{-1}=\frac{1}{(Z_1-Z_2)}\begin{bmatrix} 1 & -Z_2 \\ -1 & Z_1 \end{bmatrix} \qquad (36)$$

If the indicated matrix product of the right member of equation 35 is carried out, the result may be put into the following form:

$$[T]^n=\frac{1}{(Z_1-Z_2)}\times$$
$$\begin{bmatrix} (Z_1\mu_1^n-Z_2\mu_2^n) & -Z_1Z_2(\mu_1^n-\mu_2^n) \\ (\mu_1^n-\mu_2^n) & (-Z_2\mu_1^n+Z_1\mu_2^n) \end{bmatrix} \qquad (37)$$

If the values of the characteristic impedances given by equations 23 and 24 are substituted into equation 37, the result may be put into the convenient form:

$$[T]^n=(\mu_1^n-\mu_2^n)[T]/(\mu_1-\mu_2)-$$
$$(\mu_1^{n-1}-\mu_2^{n-1})[U]/(\mu_1-\mu_2) \qquad (38)$$

where $[U]$ is the unit matrix of the second order. This result expresses $[T]^n$ in terms of $[T]$ and its eigenvalues only. To write equation 38 in a more convenient form, let

$$\mu_1=\epsilon^{j\theta},\ \mu_2=\epsilon^{-j\theta} \qquad (39)$$

where $j=(-1)^{1/2}$.

Hence

$$(\mu_1+\mu_2)=\epsilon^{j\theta}+\epsilon^{-j\theta}=2\cos(\theta)=\text{trace}\ [T] \qquad (40)$$

If these relations are substituted into equation 38 the result may be written as follows

$$[T]^n=\frac{\sin(n\theta)}{\sin(\theta)}[T]-\frac{\sin[(n-1)\theta]}{\sin(\theta)}[U] \qquad (41)$$

It is very convenient to express the relation 41 in terms of the Chebyshev

Table I. Transmission Matrices of Fundamental Quadripoles

9	 TRANSMISSION LINE LENGTH = S	$\begin{bmatrix} \cosh(aS) & Z_0 \sinh(aS) \\ \sinh(aS)/Z_0 & \cosh(aS) \end{bmatrix}$ a = propagation constant Z_0 = characteristic impedance S = length of line
	 CASCADE OF IDENTICAL QUADRIPOLES $[T] = \begin{bmatrix} A & B \\ C & D \end{bmatrix}$ = TRANSMISSION MATRIX OF EACH QUADRIPOLE OF THE CASCADE	Transmission matrix of entire cascade of n quadripoles $\begin{bmatrix} \cosh(an) & Z_0 \sinh(an) \\ \sinh(an)/Z_0 & \cosh(an) \end{bmatrix} = [T]_n$ Provided $A = D$ (symmetric networks) $a = \cosh^{-1} A$ = propagation constant $Z_0 = (B/C)^{1/2}$ = characteristic impedance $[T]_n = S_{n-1}(x)[T] - S_{n-2}(x)U,\ A \neq D$ $S_{n-1}(x)$ = Chebyshev polynomial $x = (A+D)$, U = second order unit matrix

polynomial $S_{n-1}(x)$.[9] This polynomial is defined by the expression

$$S_{n-1}(x) = \frac{\sin(n\theta)}{\sin(\theta)},\ x = 2\cos(\theta) = \text{trace } [T] \tag{42}$$

Thus it may be seen that equation 41 may be written as equation 43

$$[T]^n = S_{n-1}x[T] - S_{n-2}(x)[U] \tag{43}$$

where x = trace $[T]$.

This concise result is very useful and has been expressed differently by several writers. Parodi[10] expresses equation 41 in terms of the Lucas functions

$$U_n(x, 1) = (\mu_1^n - \mu_2^n)/(\mu_1 - \mu_2) \tag{44}$$

The result, equation 41, may also be expressed in terms of the Gegenbauer polynomials $C_{n-1}{}'(\cos\theta)$. These polynomials are defined by the equation[11]

$$C_{n-1}{}'(\cos\theta) = \frac{\sin(n\theta)}{\sin(\theta)} \tag{45}$$

In the critical case, when

$$b = \pm 1 = (A+D)/2 \tag{46}$$

the two eigenvalues μ_1 and μ_2 become equal to b. If $b=1$, $\theta=0$; while if $b=1$, $\theta=\pi$. Both of these values of θ lead to indeterminate forms in expression 41. If the indeterminate forms are evaluated, the following results are obtained:

$$\text{If } (A+D) = \ \ 2,\ [T]^n = n[T] - (n-1)U \tag{47}$$

$$\text{If } (A+D) = -2,\ [T]^n = n[T] + (n-1)U \tag{48}$$

The case of the symmetric quadripole arises frequently in practice. In this case $A = D$ and the propagation constant a and the characteristic impedances have the values

$$\begin{aligned} a = \cosh^{-1}(A),\ Z_1 = \frac{\sinh(a)}{C},\ Z_2 = -\frac{\sinh(a)}{C} \\ = Z_0,\ Z_2 = -Z_0 = -(B/C)^{1/2} \\ = (B/C)^{1/2} \end{aligned} \tag{49}$$

The eigenvalues of $[T]$ are given by equation 20. If these values for Z_1, Z_2, μ_1 and μ_2 are substituted into equation 37 the resulting expression reduces to

$$[T]^n = \begin{bmatrix} \cosh(an) & Z_0 \sinh(an) \\ \frac{\sinh(an)}{Z_0} & \cosh(an) \end{bmatrix} \tag{50}$$

This is the familar expression for powers of the transmission matrix of a symmetric quadripole.

Transmission Matrix of Geometrically Tapered Chain of Quadripoles

Most applications of equation 43 for the powers of a transmission matrix have been treated in the discussion of wave propagation along a uniform chain of quadripoles.[1,2,6] It will now be shown how the application of this expression may be extended to a cascade of geometrically tapered quadripoles. Consider the quadripole of Fig. 2. Let k be a positive real number. The transmission matrix of the quadripole of Fig. 2 is

$$\begin{aligned} [T]_n &= \begin{bmatrix} (1+YZ) & k^{2n}Z \\ k^{-2n}Y & 1 \end{bmatrix} \\ &= \begin{bmatrix} A & k^{2n}B \\ k^{-2n}C & D \end{bmatrix} \end{aligned} \tag{51}$$

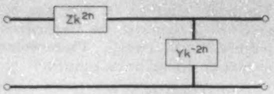

Fig. 2. Basic tapered quadripole

where, in this case, $A=(1+ZY)$, $B=Z$, $C=Y$, $D=1$.

If the index n is allowed to take on the values $n=0,1,2,3$, etc., a whole set of quadripoles of the type of Fig. 2 is obtained. Fig. 3 shows a chain of $(s+1)$ such quadripoles in which the index n has been allowed to take on the values, $n=0, 1,2,3,\ldots k$. The impedances and admittances of this chain of quadripoles are given by

$$Z_n=Zk^{2n},\quad Y_n=Yk^{-2n} \tag{52}$$

The transmission matrix $[T(s+1)]$ of the entire chain of $(s+1)$ quadripoles of the type of Fig. 2 is given by

$$[T(s+1)]=[T]_0[T]_1[T]_2[T]_3\ldots[T]_s \tag{53}$$

Now it is easy to see that the transmission matrix $[T]$ of the nth quadripole given by equation 51 may be factored in the form

$$[T]_n=\begin{bmatrix} k^n & 0 \\ 0 & k^{-n}\end{bmatrix}\begin{bmatrix} A & B \\ C & D\end{bmatrix}\begin{bmatrix} k^{-n} & 0 \\ 0 & k^n\end{bmatrix} \tag{54}$$

Let

$$[P]_n=\begin{bmatrix} k^n & 0 \\ 0 & k^{-n}\end{bmatrix},\quad [Q]_n=\begin{bmatrix} k^{-n} & 0 \\ 0 & k^n\end{bmatrix}=[P]_n^{-1} \tag{55}$$

Then, equation 54 may be written

$$[T]_n=[P]_n[T][Q]_n$$

where

$$[T]=\begin{bmatrix} A & B \\ C & D\end{bmatrix}=[T]_0 \tag{56}$$

The matrices $[P]_n$ and $[Q]_n$ have the following important property:

$$[P]_m[P]_n=[P]_{(m+n)},\quad [Q]_m[Q]_n=[Q]_{(m+n)} \tag{57}$$

Since $[P]_n=[Q]_n^{-1}$, it follows that

$$[P]_{n+1}=[P]_n[P]_1=[Q]_n^{-1}[P]_1 \tag{58}$$

Hence

$$[Q]_n[P]_{n+1}=[Q]_n[Q]_n^{-1}[P]_1=[P]_1 \tag{59}$$

The transmission matrix of the cascade of $(s+1)$ quadripoles may be obtained by substituting equation 56 into equation 53 and obtaining the following expression:

$$[T(s+1)]=([P]_0[T][Q]_0)([P]_1[T][Q]_1)\ldots([P]_s[T][Q]_s) \tag{60}$$

By the use of equation 59 this may be reduced to

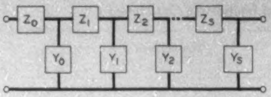

Fig. 3. Tapered chain of quadripoles

$$[T(s+1)]=([T][P]_1)^{s+1}[Q]_{s+1} \tag{61}$$

Now let

$$[T][P]_1=\begin{bmatrix} A & B \\ C & D\end{bmatrix}\begin{bmatrix} k & 0 \\ 0 & k^{-1}\end{bmatrix}=\begin{bmatrix} Ak & Bk^{-1} \\ Ck & Dk^{-1}\end{bmatrix}=[M] \tag{62}$$

It is then seen that the transmission matrix of the $(s+1)$ geometrically tapered quadripoles given by equation 60, may be written in the form

$$[T(s+1)]=[M]^{s+1}[Q]_{s+1} \tag{63}$$

Therefore, as a consequence of equation 43, the following may be written:

$$[T(s+1)]=S_s\mathbf{x}[M][Q]_{s+1}-S_{s-1}\mathbf{x}[Q]_{s+1} \tag{64}$$

where $S_s\mathbf{x}$ is the Chebyshev polynomial defined by equation 42, and

$$x=\text{trace }[M]=(Ak+Dk^{-1}) \tag{65}$$

This is a concise expression for the transmission matrix of the tapered chain of quadripoles of Fig. 3.

Chain of Symmetric Networks Having the Same Characteristic Impedance

As another example of a chain of nonuniform networks, consider the symmetric T network of Fig. 4. The transmission matrix of this network is

$$[T]_n=\begin{bmatrix} (1+Z_nY_n) & (2Z_n+Y_nZ_n^2) \\ Y_n & (1+Z_nY_n)\end{bmatrix}=\begin{bmatrix} A_n & B_n \\ C_n & A_n\end{bmatrix} \tag{66}$$

The characteristic impedance of this network Z_0 is given by

$$Z_0=(B_n/C_n)^{1/2}=(Z_n^2+2Z_n/Y_n)^{1/2} \tag{67}$$

Now, if Y_n is chosen, so that

$$Y_n=2Z_n/(Z_0^2-Z_n^2),\quad Z_0\neq Z_n \tag{68}$$

it is seen on substituting this expression into equation 67 that the characteristic impedance is Z_0 and is independent of the index n.

This choice of Y_n yields from equation 66, equation 69 following:

$$A_n=(1+Z_nY_n)=(Z_0^2+Z_n^2)/(Z_0^2-Z_n^2)$$
$$B_n=2Z_n+Y_nZ_n^2=2Z_nZ_0^2/(Z_0^2-Z_n^2)$$
$$C_n=Y_n=2Z_n/(Z_0^2-Z_n^2) \tag{69}$$

If the propagation constant a_n of this T section is defined by the equation

$$\cosh(a_n)=A_n=(Z_0^2+Z_n^2)/(Z_0^2-Z_n^2) \tag{70}$$

the following equations are easily obtained:

$$\sinh(a_n)=2Z_0Z_n/(Z_0^2-Z_n^2) \tag{71}$$

$$B_n=Z_0\sinh(a_n),\quad C_n=\sinh(a_n)/Z_0 \tag{72}$$

The transmission matrix of the network of Fig. 4 may therefore be written in the following form:

$$[T]_n=\begin{bmatrix} \cosh(a_n) & Z_0\sinh(a_n) \\ \dfrac{\sinh(a_n)}{Z_0} & \cosh(a_n)\end{bmatrix} \tag{73}$$

Therefore, if some definite value for Z_0 is chosen and Y_n is adjusted to satisfy equation 68, then by allowing Z_n to take the successive values $Z_1,Z_2,\ \ldots\ Z_r$, we obtain a set of r quadripoles of the type of Fig. 4 whose propagation constants $a_1,a_2,a_3,\ldots a_r$ are different but whose characteristic impedance is the same and is equal to Z_0.

The transmission matrix $[T(r)]$ of a cascade of r such quadripoles is given by

$$[T(r)]=[T]_1[T]_2[T]_3\ldots[T]_r \tag{74}$$

If the chain of matrices of equation 74 are multiplied together and use is made of the addition equations of the hyperbolic sine and hyperbolic cosine functions, the following concise result is obtained for transmission matrix of the cascade of r symmetric T networks of Fig. 4.

$$[T(r)]=\begin{bmatrix} \cosh(a_1+a_2+\ldots+a_r) & Z_0\sinh(a_1+a_2+\ldots+a_r) \\ \dfrac{\sinh}{Z_0}(a_1+a_2+\ldots+a_r) & \cosh(a_1+a_2+\ldots a_r)\end{bmatrix} \tag{75}$$

It is thus seen that the propagation constant $a(r)$ for the entire cascade is given by

$$a(r)=(a_1+a_2+\ldots+a_r) \tag{76}$$

where

$$a_n=\cosh^{-1}[(Z_0^2+Z_n^2)/(Z_0^2-Z_n^2)],\quad n=1,2,3,\ldots r \tag{77}$$

Hence equation 75 may be written concisely in the form

$$[T(r)]=\begin{bmatrix} \cosh a(r) & Z_0\sinh a(r) \\ \dfrac{\sinh a(r)}{Z_0} & \cosh a(r)\end{bmatrix} \tag{78}$$

Use of Matrices in Polyphase Systems

As is well known, matrix algebra is very useful in the analysis of certain classes of polyphase systems.[5] The intimate connection between certain transformations used by the power engineer and the eigenvalues and eigenvectors of the impedance matrices that arise in practical problems is not quite fully appreciated by many electrical engineers. In this section the basic ideas involved are presented as an extension of the analysis of the single-phase quadripole.

To fix the ideas in question, consider an apparatus with four terminals as shown in Fig. 5. Three of the terminals are to be connected to the lines of a 3-phase source and the fourth to the grounded neutral of the system. Let the complex line currents be I_1,I_2,I_3 and the complex line-to-ground voltages E_1,E_2,E_3 measured as shown in Fig. 5. By Kirchhoff's laws, the following equations may be written

$$\begin{bmatrix} E_1 \\ E_2 \\ E_3 \end{bmatrix} = \begin{bmatrix} Z_{11} & Z_{12} & Z_{13} \\ Z_{21} & Z_{22} & Z_{23} \\ Z_{31} & Z_{32} & Z_{33} \end{bmatrix} \begin{bmatrix} I_1 \\ I_2 \\ I_3 \end{bmatrix} \tag{79}$$

or, more concisely

$$(E)=[Z](I) \tag{80}$$

In a very important class of electrical circuits which includes the equivalent circuits of 3-phase synchronous and induction machines with smooth air gaps,[12,13] the impedance matrix $[Z]$ of equation 80 has the general form

$$[Z]=\begin{bmatrix} Z_1 & Z_2 & Z_3 \\ Z_3 & Z_1 & Z_2 \\ Z_2 & Z_3 & Z_1 \end{bmatrix} \tag{81}$$

This matrix is symmetric about the second principal diagonal. A matrix that exhibits this type of symmetry is called a circulant matrix in the mathematical literature.[14] To determine the eigenvalues and eigenvectors of the matrix $[Z]$ it is necessary to follow the same procedure as that in the "Eigenvalues and Eigenvectors of Transmission Matrix" and to determine for what values of the parameter 9 the following relation is satisfied:

$$[Z]\mathbf{x}=\mu\mathbf{x} \tag{82}$$

where x is a column matrix or vector whose elements are x_1,x_2,x_3.

Equation 82 may be written in the form

$$([Z]-\mu[U])\mathbf{x}=(0) \tag{83}$$

where $[U]$ is the unit matrix of the third order and (0) is the third-order zero vector. Since equation 83 represents a homogeneous set of equations in the unknowns x_1,x_2,x_3, the following determinant must vanish:

$$\det([Z]-\mu[U]) = \begin{vmatrix} (Z_1-\mu) & Z_2 & Z_3 \\ Z_3 & (Z_1-\mu) & Z_2 \\ Z_2 & Z_3 & (Z_1-\mu) \end{vmatrix} = D = 0 \tag{84}$$

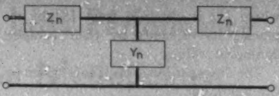

Fig. 4. Symmetric T-network

This is the characteristic equation of the impedance matrix $[Z]$; the possible values of μ satisfied by this equation are the eigenvalues of $[Z]$.

A determinant that exhibits the symmetry shown by D of equation 84 is called a circulant in the mathematical literature.[14] It is easy to show that the determinant D may be factored in the form

$$D=[(Z_1-\mu)+Z_2+Z_3][(Z_1-\mu)+a^2Z_2+aZ_3][(Z_1-\mu)+aZ_2+a^2Z_3] \tag{85}$$

where a = exponent $(2\pi j/3)$, the complex cube root of unity. The three eigenvalues of the circulant matrix $[Z]$ of equation 81 are therefore

$$\mu_1=(Z_1+Z_2+Z_3)$$
$$\mu_2=(Z_1+a^2Z_2+aZ_3),\quad a=\exp(2\pi j/3) \tag{86}$$
$$\mu_3=(Z_1+aZ_2+a^2Z_3)$$

It may be noted that the three eigenvalues have the dimensions of impedances.

To each eigenvalue μ_i there corresponds an eigenvector $\mathbf{x}_i$ which must satisfy an equation of the type of equation 82, or

$$[Z]\mathbf{x}_i=\mu_i\mathbf{x}_i,\quad i=1, 2, 3 \tag{87}$$

If the first element of each column $\mathbf{x}_i$ is chosen to be unity, then equation 87 fixes the other numbers of the columns and it may be seen that the three eigenvectors of $[Z]$ may be taken to be

$$\mathbf{x}_1=\begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix},\quad \mathbf{x}_2=\begin{bmatrix} 1 \\ a^2 \\ a \end{bmatrix},\quad \mathbf{x}_3=\begin{bmatrix} 1 \\ a \\ a^2 \end{bmatrix} \tag{88}$$

The square matrix $[S]$ formed from the three eigenvectors in the form

$$[S]=[\mathbf{x}_1\mathbf{x}_2\mathbf{x}_3]=\begin{bmatrix} 1 & 1 & 1 \\ 1 & a^2 & a \\ 1 & a & a^2 \end{bmatrix} \tag{89}$$

is the modal matrix of the circulant impedance matrix $[Z]$. The three equations

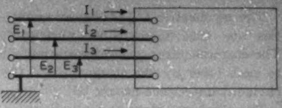

Fig. 5. Three-phase network

87 may now be written as the single matrix equation

$$[Z][S]=[S][d] \tag{90}$$

where $[d]$ is the diagonal matrix of the eigenvalues,

$$[d]=\begin{bmatrix} \mu_1 & 0 & 0 \\ 0 & \mu_2 & 0 \\ 0 & 0 & \mu_3 \end{bmatrix} \tag{91}$$

It is thus seen that as a consequence of equation 90 the circulant matrix $[Z]$ may be written in the following diagonal form:

$$[S]^{-1}[Z][S]=[d] \tag{92}$$

The modal matrix $[S]$ is of great importance in the theory of symmetrical components[5]; it has the following important properties:

$$\det[S]=3(a-a^2)=3j\sqrt{3} \tag{93}$$

$$[S]^{-1}=\frac{1}{3}\begin{bmatrix} 1 & 1 & 1 \\ 1 & a & a^2 \\ 1 & a^2 & a \end{bmatrix}=\frac{1}{3}[\bar{S}] \tag{94}$$

where $[\bar{S}]$ is obtained from $[S]$ by replacing each element by its complex conjugate.

In the theory of symmetrical components, the following linear transformations are introduced:

$$\mathbf{i}_s=[S]^{-1}(I)=\begin{bmatrix} i_1 \\ i_2 \\ i_3 \end{bmatrix},\quad \mathbf{e}_s=[S]^{-1}(E)=\begin{bmatrix} e_1 \\ e_2 \\ e_3 \end{bmatrix} \tag{95}$$

The elements of the vectors $\mathbf{i}_s$ and $\mathbf{e}_s$ which are here denoted by small letters are the symmetrical components of the currents $\mathbf{I}$ and the potentials $\mathbf{E}$ respectively. As a consequence of the transformations, equation 95, the physical current and potential vectors are given by the inverse transformations in the form

$$\mathbf{I}=[S]\mathbf{i}_s,\quad \mathbf{E}=[S]\mathbf{e}_s \tag{96}$$

If these vectors are substituted into equation 80 the resulting equation is

$$[S]\mathbf{e}_s=[Z][S]\mathbf{i}_s \tag{97}$$

or

$$\mathbf{e}_s=([S]^{-1}[Z][S])\mathbf{i}_s=[d]\mathbf{i}_s \tag{98}$$

If this matrix equation is expanded, it may be seen that

$$e_1=\mu_1i_1,\quad e_2=\mu_2i_2,\quad e_3=\mu_3i_3 \tag{99}$$

The symmetrical component quantities are thus seen to be uncoupled. The corresponding quantities are related to each other by the eigenvalues of the circulant impedance matrix $[Z]$.

The 3-phase theory just discussed may be easily extended to n-phase systems whose impedance matrices exhibit circulant symmetry.[14]

Consider an n-phase network characterized by a circulant impedance matrix of the nth order of the form

$$[Z]_n=\begin{bmatrix} Z_1 & Z_2 & Z_3\ldots Z_n \\ Z_n & Z_1 & Z_2\ldots Z_{n-1} \\ \multicolumn{3}{c}{\cdots\cdots\cdots\cdots\cdots\cdots} \\ Z_2 & Z_3 & Z_4\ldots Z_1 \end{bmatrix} \tag{100}$$

It may be shown that the eigenvalues of $[Z]_n$ are given by

$$\begin{aligned} \mu_1&=(Z_1+Z_2+Z_3+\ldots+Z_n) \\ \mu_2&=(Z_1+a^{n-1}Z_2+a^{n-2}Z_3+\ldots+aZ_n) \\ &\vdots \\ \mu_n&=(Z_1+aZ_2+a^2Z_3+\ldots+a^{n-1}Z_n) \end{aligned} \tag{101}$$

where in this case the number a is the complex nth root of unity given by

$$a=\exp(2\pi j/n) \tag{102}$$

where exp = exponent.

The modal matrix of $[Z]$ is given by the equation

$$[S]=\begin{bmatrix} 1 & 1 & 1\ldots\ldots1 \\ 1 & a^{n-1} & a^{n-2}\ldots a \\ \vdots & & \\ 1 & a & a^2\ldots\ldots a^{n-1} \end{bmatrix} \tag{103}$$

The typical element S_{pq} of $[S]$ may be written in the form

$$S_{pq}=a^{(1-p)(q-1)},\ a=\exp(2\pi j/n) \tag{104}$$

The inverse of $[S]$ is given by

$$[S]^{-1}=\frac{1}{n}[\bar{S}] \tag{105}$$

where $[\bar{S}]$ is obtained from $[S]$ by replacing its elements by their complex conjugate values.

The diagonal form of $[Z]_n$ is given by the following

$$[S]^{-1}[Z]_n[S]=[d_n] \tag{106}$$

where

$$[d_n]=\begin{bmatrix} \mu_1 & 0 & 0 & 0 & 0\ldots0 \\ 0 & \mu_2 & 0 & 0 & 0\ldots0 \\ \vdots & & & & \\ 0 & 0 & 0 & 0 & 0\ldots\mu_n \end{bmatrix} \tag{107}$$

If the current and potential vectors $\mathbf{I}$ and $\mathbf{E}$ of the nth phase polyphase system are related by the equation

$$\mathbf{E}=[Z](I) \tag{108}$$

Symmetrical component current and potential vectors are possible, as in equation 95 with the exception that $\mathbf{i}_s$ and $\mathbf{e}_s$ are now column matrices of n elements i_r and e_r, and the transformation matrix is now equation 105.

These linear transformations reduce equation 108 to the form

$$\mathbf{e}_s=([S]^{-1}[Z]_n[S])\mathbf{i}_s=[d_n](i)_s \tag{109}$$

and hence

$$e_r=\mu_r i_r,\ r=1, 2, 3, \ldots n \tag{110}$$

and the symmetrical component quantities are seen to be uncoupled.

The importance of transformations of the type in equation 95 in electrical engineering is due to the common occurrence of impedance matrices of the circulant type in practical power networks. Other types of linear transformations have been suggested and used to solve problems in which the impedance matrix has symmetry other than circulant symmetry.[15]

Impedance and Return Loss Performance of Telephone Plant in Metropolitan Areas

L. B. BOGAN
MEMBER AIEE

THE FUNDAMENTAL DESIGN and successful operation of the nation-wide switching plan assumes a specified return loss performance of the metropolitan area plant. Metropolitan area plant includes the terminating trunks and subscriber loops which are involved at each end of an intercity telephone connection. The return losses not only must be adequate over the voice band as a whole in order to limit echo currents, but also must meet certain minimums at individual frequencies to avoid singing conditions.

The switching plan now in effect provides for more links and lower losses than the plan previously in effect. To operate at these lower losses with the same echo and singing margins, it is necessary to improve the terminal echo and singing return losses with respect to the conditions prevailing under the earlier plan.

This paper discusses the means of achieving the improved return losses, and reviews the limited test results which are now becoming available. First of all, however, it is thought that a better understanding of the situation will be realized if some attention is devoted to the nature of echo and singing and then to the peculiarities of the impedances of the metropolitan area plant as seen from the point of interconnection with the long intercity trunks.

Echo and Singing

It is never amiss to review the considerations controlling echo and singing. An understanding of the various features involved is fundamental for an appreciation of the techniques to be applied and the desired performance objectives.

Two factors contribute to the seriousness of an echo condition. One is magnitude of the returned, or echo, current and the other is its delay time. This paper will be concerned only with the factors contributing to the magnitude. The time factors of echo and the other criteria of intertoll trunk design are covered in other publications.[1,2]

Fig. 1, in its upper half, illustrates an over-all connection between two metropolitan areas separated by 1,000 miles. Two 500-mile carrier links, with a 4-wire switch at the intermediate office, are assumed to establish this connection. The objective loss design of this type of plant today is indicated by the db (decibel) quantities. In the lower half of Fig. 1 the significant features to observe are that echo is a single terminal phenomenon, and that singing requires the co-operation of both ends.

A low echo return loss at one terminal will promote echo to the far talker regardless of the magnitude of the echo return loss at the talker's own terminal. Also, it will be evident that as lower trunk losses become possible, the echo return losses at the terminals must be increased to maintain the same loss in the echo path.

Singing will occur when the return losses at the same frequency at both terminals approach zero and the net losses of the transmission medium, due to circuit variations, drift to gains. The significant factor here is that for a singing condition, the near-zero return loss at each terminal must be at the same frequency. It is possible to have a zero return loss at a low frequency at one terminal and a zero return loss at a somewhat higher frequency at the other terminal without singing jeopardy, even with the transmission path in a condition of gain.

Broadly speaking, return loss is a measure of the similarity or dissimilarity, depending on the point of view, of two impedances. The nearer the two impedances approach identity of magnitude and angle, the higher the return loss in decibels. Table I indicates the effects of magnitude and angular deviations individually on the return loss. The decibel values will provide a helpful background for the ensuing discussions.

For 2-wire switching systems the reference impedance condition for our terminal plant is the compromise network in the terminating sets of the intercity circuits. Generally, this is 900 ohms +2 mf (microfarads) for a crossbar tandem system, and 600 ohms +2 mf for the other types of 2-wire switching toll systems.

At 4-wire switching systems, where the hybrid coil to terminate the 4-wire intercity facility is permanently associated with the terminating trunk, compromise networks are not necessary. A precision network corresponding to the particular trunk facility may be used to obtain greatly improved return loss performance.

The problem in 2-wire switching is to make the heterogeneous array of impedances of the terminal plant somehow approach an impedance of 900 ohms+2 mf (or 600 ohms+2 mf) over the voice-frequency band.

As designed over the years, the return losses of the existing plant, against the compromise networks just referred to, appear to be a distribution having an average of 11 db with a sigma (standard deviation) of 3 db for the echo range. Singing points also appear to be a distribution, having an average of 6 and a sigma of 2 db. Tests made over the years have fairly well substantiated these figures. They have therefore been taken as the base values from which to work, if the singing and echo margins of the plant are to be maintained as the trunk losses are engineered for the proposed switching plan.

Within the past few years, one of the new techniques for the design of intercity trunks has been the omission of the 2-db pad loss in each terminating connection. The presence of this 2-db pad theoretically increases the average return loss of the terminating plant by 4 db (twice the loss of the pad). Consequently to satisfy the objectives with the new technique which omits this pad, or its equivalent loss, it is necessary to find a method of building an additional 4 db into the return loss of the terminating plant.

Another feature of the new approach in transmission design philosophy is the specification of performances in terms of distributions of various contributing factors rather than as a single "go, no-go" value. Methods of implementing this

concept in layout and maintenance are outstanding problems.

Loop Plant

The loop is identified as the channel extending from the serving central office to the subscriber's station, including the equipment permanently associated with the facilities at each end.

Loop facilities commonly encountered within a single central office area may be of 26, 24, and 22 gauge and, to a limited extent in older offices, 19 gauge. The lengths encountered obviously can start at practically zero for a station within the same building as the central office up to the maximum loop in the office. Loops up to 18 kf (kilofeet) are generally nonloaded, and those over 18 kf are loaded for the entire distance. Loaded loops present a somewhat different impedance condition from those to be presented in the following sections of this paper.

The variety of impedances in the loop plant, including the office battery supply circuit and the telephone set, are therefore due to the almost infinite variations resulting from the combination of lengths, gauges, and frequencies. Figs. 2 and 3 have been prepared to illustrate the variations within 24-gage nonloaded loops due to frequency and length.

Table I. Return Loss of Various Impedances Versus a Reference Impedance

Any Impedance in Terms of Reference Impedance	Return Loss In Db Versus Reference Impedance $Z\underline{/\theta}$	
$Z\underline{/\theta}$	∞	showing effect of variation in impedance magnitude only
$0.9Z\underline{/\theta}$ (or $1.11Z\underline{/\theta}$)	26	
$0.8Z\underline{/\theta}$ (or $1.25Z\underline{/\theta}$)	19	
$0.5Z\underline{/\theta}$ (or $2Z\underline{/\theta}$)	10	
$0.25Z\underline{/\theta}$ (or $4Z\underline{/\theta}$)	4	
$Z\underline{/\theta \pm 5°}$	27	showing effect of variation in impedance angle only

$Z\underline{/\theta \pm 20°}$	15	
$Z\underline{/\theta \pm 45°}$	8	
$Z\underline{/\theta \pm 70°}$	3	

Fig. 2 shows four curves marked respectively, 0, 1, 10, and 20 kf. Each of these curves shows the effect on impedance as the frequency is changed from 300 to 3,000 cycles. The curve marked 0 kf is the variation over the frequency range of the input impedance of a battery supply repeating coil and a subscriber set with no intermediate line facility. In the other three curves these two terminations are separated by 1, 10, and 20 kf of 24 gage. Intermediate frequency points of 500, 1,000, and 2,000 cycles are indicated.

Fig. 3 shows the variation at three frequencies (300, 1,000, and 3,000 cycles) of impedances of 24-gage loops as they are extended from 0 to 20 kf. The impedance variations due to length and frequency of 24-gage alone blanket to a considerable extent the impedance field shown in the figures.

In Fig. 4, the 1,000-cycle impedance of 24-gage nonloaded facilities has been reproduced from Fig. 3 and, for comparison, curves for 19-, 22-, and 26-gage nonloaded loops from 0 to 20 kf are produced to suggest the range of the impedance. This is unduly simplified, since most of the loops have at least two gages and often more. In addition, in other than metropolitan areas, loop plant may include some bare copper or iron wire, involving other impedance contrasts. One problem currently being considered involves the poor impedance characteristics resulting from a combination of cable, open-wire, and magneto station sets.

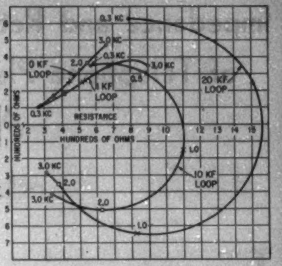

Fig. 2. Input impedance of 0-, 1-, 10-, and 20-kf 24-gage loops as the frequency is varied from 0.3 to 3.0 kc

Also to complicate the situation, the effect on impedance of substituting the 500-type set (the equalized set introduced as standard in the Bell System in the late 1940's,[3]) for the *F1A* set (the predecessor set which has been standard since about 1938[4]) on 24-gage is indicated. This shows rather radical impedance departure from the *F1A* set for short loop lengths. In future years, this change will be significant as the plant becomes saturated with 500-type sets. However, for the present, the problem is still mostly concerned with *F1A* sets since zoning specifies the use of 500-type sets on long loops where impedances fairly well conform to those shown with the *F1A* sets.

Trunk Plant

A terminal trunk is usually involved between an intercity circuit and the subscriber loop. This trunk is usually loaded and today *H88* loading (88-millihenry coils spaced at 6,000 feet) predominates. The gauge of the facility, however, may

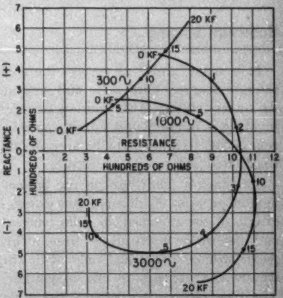

Fig. 3. Input impedance at 0.3, 1.0, and 3.0 kc as 24-gage loops are extended from 0 to 20 kf

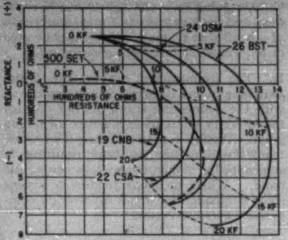

Fig. 4. Input impedance at 1.0 kc as 19-, 22-, 24-, and 26-gage loops are extended from 0 to 20 kf

be 19, 22, or 24, with possibility of 26 gage in some areas. Eventually a very large percentage of these trunks may be designed with repeaters of the negative impedance type.[5] The use of repeaters will add other complexities to terminal impedances. Also the use of carrier systems for these terminating trunks is becoming more common, but the present discussion will be concerned with only the voice-frequency facilities which predominate in the metropolitan plant.

The impedances of 19, 22, and 24 *H88*-loaded trunk facilities are not greatly dissimilar and the impedance of the 22 gage will serve also as a fair approximation of the other two.

Fig. 5 shows the mid-section impedance of a *22H88* pair and what happens to this input impedance when discontinuities or terminations are applied at a finite distance, corresponding to a practical trunk length.

Precision Network. This curve is the characteristic mid-section impedance of an infinite length of the facility. For present purposes this may be analyzed as a 24-kf trunk (four loading coils) terminated with the precision network for this type of facility properly adjusted for end section.

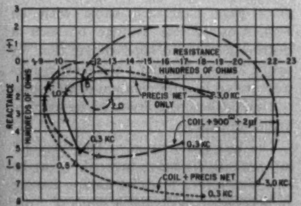

Fig. 5. Input impedance of 24-kf 22H88 trunk as frequency is varied from 0.3 to 3.0 kc, for three terminations other than loop

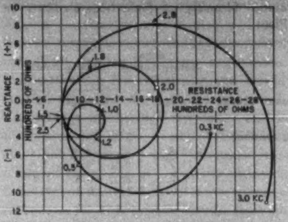

Fig. 6. Input impedance of 24-kf 22H88 trunk, terminated with a 20-kf loop, as frequency is varied from 0.3 to 3.0 kc

Coil Plus Precision Network. This curve shows the results of inserting a 1-to-1-ratio repeating coil between the 24-kf trunk and the precision network. It will be noted that a small loop is thrown into the characteristic at about 2 kc but that the largest effect on the impedance is at low frequencies, caused by the repeating coil. This curve also demonstrates that at the higher frequencies, the repeating coil is almost electrically transparent.

Coil Plus Compromise Network Termination. The precision network at the far end has been replaced with a compromise network of 900 ohms+2 mf, retaining the repeating coil. While there has been some additional low-frequency effect, and the loop has been enlarged, the major change in impedance has taken place at the frequencies above 2,000 cycles. At the higher frequencies the resistive component of the cable impedance is steadily rising whereas that of the termination remains unchanged. The junction irregularity increases with frequency.

Trunks Terminated in Loops

In Fig. 5, the sensitiveness of the input impedance of a trunk with any structural variation at a distant point is demonstrated. The irregularities assumed were comparatively nominal. Fig. 6 indicates the effect on the sending-end impedance of this trunk when the terminations beyond the repeating coil are replaced by a 20-kf loop of 24 gage. (At present, 18 kf is the maximum recommended nonloaded loop in the Bell System. The computations for 20 kf were available from an earlier study and are used in this instance as a fair approximation of a limiting nonloaded loop.) The relative scales of both resistance and reactance in this figure and subsequent figures are half those of Figs. 2 through 5.

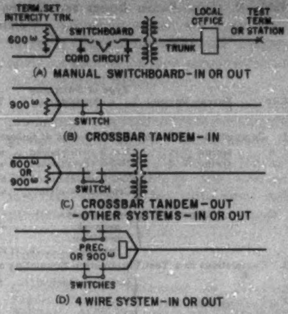

Fig. 8. Types of terminations at switching points

The gyrations in this curve are just short of fantastic. There appears to be a fair control of the impedance in the range of 500 to 2,500 cycles, but completely loose ends at 300 and 3,000 cycles. In this figure no repeating coil is involved at the input of the trunk. For plant conditions not requiring repeating coils this is substantially the best low-frequency impedance obtainable unless a low-frequency

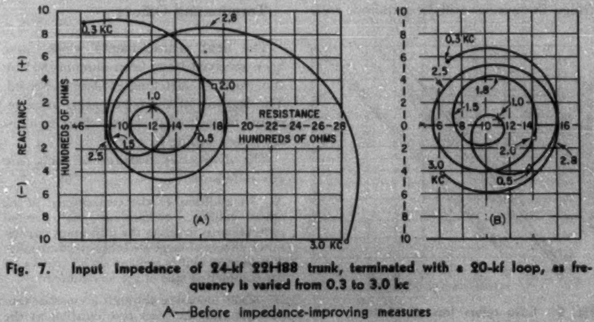

Fig. 7. Input impedance of 24-kf 22H88 trunk, terminated with a 20-kf loop, as frequency is varied from 0.3 to 3.0 kc

corrector is used. This consists of a simple *RLC* series circuit tuned at about 250 cycles with a resistance of about 2,000 ohms shunted across the trunk input. With a low-frequency corrector the 300-cycle impedance would be reduced to the order of 1,000 ohms with a small angle.

All operating conditions, other than completing from crossbar tandems, involve a repeating coil at the input of the trunk. Traditionally, in the Bell System, the repeating coils have had mid-point capacitors of 4 mf in both windings.

In Fig. 7(A) an input repeating coil has been added to Fig. 6. Only the low-frequency impedances are affected, but it has been a major change. Fig. 7(A) is representative of the plant conditions producing the 11-db echo return loss and the 6-db singing point.

To improve the singing and echo performance of this type of impedance characteristic a radical operation on the fringe frequencies will be required, with perhaps only a nominal improvement over the body of the characteristic. The features found to produce these improvements were: 1. the substitution of a 1-mf capacitor for the 4-mf capacitor on the input side of the input repeating coil, and 2. the application of the impedance compensator (IC) technique to the loaded end section of the trunk.

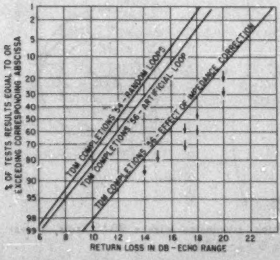

Fig. 9. Echo return loss distributions: incoming connections at crossbar tandem office

Fig. 7(B) shows the results of applying these two measures. Theoretically this appears to have achieved the desired improvements of echo and singing return losses by the wanted amounts.

Only actual measurements of modified plant layouts can determine to what extent the theoretical improvements developed in the foregoing have been realized. Fortunately, some field measurements are now becoming available; these are reviewed in the following section.

Switching Arrangements at Terminating Offices

The field measurements which have been received have been summarized by the class of switching system involved. The features of the terminating arrangements of each of these switching systems are shown in Fig. 8.

The distinctive features of each case are as follows:

A. In addition to the capacitance of the office cabling, completion via manual switchboards involves the important capacitance effects of large switchboard multiples. A repeating coil is present on all trunks on the completing side of the switchboard.

B. Calls incoming through a crossbar tandem provide the least complication at the terminating office.

C. Outgoing only through a crossbar tandem, and both IN and OUT connecting trunks at other 2-wire systems, such as step-by-step or no. 5 crossbar, require repeating coils.

D. The terminating set at the 4-wire switching point is permanently associated with the connecting trunk instead of with the intercity trunk as at a 2-wire switching point. Precision networks are used when trunk facilities are involved resulting in substantially higher return loss across the band. Where no trunk facility or a very short nonloaded facility is involved, a compromise network is used.

Summary of Field Measurements

Table II summarizes the results of echo return loss and singing point measurements made on working terminal plant.

Part 1 of this table shows, for the various types of switching systems, results of over-all measurements on random trunks and random subscriber stations in three different cities. The range of these results is comparatively narrow and conforms reasonably well to the anticipated distributions of echo and singing, with an average and sigma of the former of 11 and 3 db, and of the latter of 6 and 2 db respectively. Even the results for the 4-wire switching system with the precision network, if adjusted for the 10-db gain which may be applied, also fall in the middle of this range, becoming 12.7 db.

Parts 2 and 3 of Table II are measurements on random trunks, but only to two types of terminations, for the purpose of reviewing the over-all situation and setting up a background for specifying maintenance techniques. The problem is to find a termination available on a dial-up basis, which would provide the best reference, and the test objectives for this selected reference. Obviously, with a fixed termination the sigma should be less, though the average may be better or worse than the actual loop distributions, depending on the type of termination.

Part 2 tests were made to a termination consisting of an artificial loop of 1.5 miles of 24-gage nonloaded cable with an *F1A* subset. The average of such a distribution should approximate that for actual loops. In Part 3 the same trunks were tested to a termination of 900 ohms +2 mf. This was expected to average higher and did so.

The test termination of 900 ohms+2 mf currently is being favored, with the objective return loss distribution having an average of 18 db and a sigma of 2 db. However, this termination has some limitations unless all trunks appear at half-section impedance at the junction with the termination. With end sections of other than half-section impedance it will be necessary to work out different reference test values, which is undesirable.

Considerations are now being given to the relative costs and advantages of terminating all trunks at half-section. Increasingly wider use of the negative impedance repeaters which operate best with half-section cable impedance might make this a practical future technique.

The only comparative results currently available of the effect of using IC, one of the improvements already discussed, are shown under the crossbar tandem items in Parts 2 and 3 of Table II. Fig. 8(B) applies to these groups, because all were incoming through the tandem. The same trunks are not involved in comparative tests. Tests were made in the midst of a conversion program and different trunk groups are included in the classes of those with and without IC. Since only *H88* facilities are compared, there is no question that the approximately 4-db difference is a direct improvement resulting from the use of IC.

It will be noted that only a nominal singing improvement was obtained but this was expected since the IC alone does not affect the low-frequency impedance. Singing at the low-frequency end would control after the high end is improved. The change in the high-frequency end is illustrated by Figs. 6 and 7(B), while the low-frequency end remains unchanged as in Fig. 6. Further study is being given to the use of low-frequency correctors for this type of trunk, since no repeating coil is involved. Sufficient field measurements are not yet available to permit a report on the effectiveness of the improvements anticipated by the change in the capacitor in the repeating coil from 4 to 1 mf.

Fig. 9 shows the distributions of the echo return losses incoming at crossbar tandems at city C. Included for reference are the 1954 survey results as well as the 1956 comparative results.

The wide sigma for the 1956 results with the test loop termination is disturbing. Investigation shows it due mainly to a wide distribution of the averages of the groups, rather than to wide distributions within each group. To illustrate this, the arrow indicators under the right-hand curve of Fig. 9 represent the average point for each of the nine groups included in the over-all distribution.

Identification of the plant conditions producing the spread in results among the groups tested, and the improvement of the lower values to reduce the over-all spread, and incidentally the average, now lies ahead. This work may well produce the material for another paper.

Discussion

Arthur F. Rose (American Telephone and Telegraph Company, New York, N. Y.): Mr. Bogan's paper and the related papers[1,2] give an excellent picture of the problems involved in the establishment of nation-wide toll telephone service in the United States. The objective of adequate transmission between any two telephones in the country has been shown to be obtainable by proper design and good maintenance within the limitations imposed by economic considerations. I should like to emphasize some of the practical aspects involved in carrying out these objectives.

Mr. Bogan's paper deals with the terminal conditions and the steps required to meet the necessary requirements. It is important to point out that this is a co-operative matter, which means that the terminal office with poor impedance conditions does not suffer as much as the distant party whose echo is increased if the return loss objectives are not met. Smooth uniform terminal impedances are the result of careful checks and intensive activities to improve poor results, as may be seen by the spread between the cities shown in Fig. 10, a chart presented by Mr. Bogan at the time that his paper was read.

Engineering and design procedures which are under the control of the telephone company, such as attention to accurate load coil spacing, adjustment of compensators, and building out where necessary, are not enough. The telephone companies must deal with reliable manufacturers whose product is uniform and dependable. For example, there is little advantage in laying out the load coil sections to 2% accuracy if the inductance of the coils or if the capacity of the cable deviate from their nominal values by a much greater percentage than this.

Likewise, if telephone repeaters are used on the trunk circuits they should be of the type which does not introduce substantial irregularity. The advantages of the Western Electric Company's *E2-3* repeater in this respect was discussed by me in 1954.[3] The simple series-type of negative impedance repeaters are, of course, entirely unsatisfactory.

Measurements of Steep-Front Impulse Waves with an Isolated Screen Room Installation

C. J. MILLER, JR.
FELLOW AIEE

J. F. WITTIBSCHLAGER
ASSOCIATE MEMBER AIEE

THE MEASUREMENT of steep-front impulse waves, when the time to flashover is less than 1 microsecond (μsec), presents problems seldom encountered in ordinary testing where flashover generally occurs on the tail of a conventional $1^1/_2\times$ 40 μsec wave.

In the fractional microsecond range, the voltage applied to the test specimen is generally increasing at a rapid rate at the instant flashover occurs. This means that the current through a resistor potential divider is likewise increasing at a corresponding rate, and hence the residual inductance in each element of this divider will generate an $L\,dI/dt$ voltage which is superimposed upon the IR voltage of the element. If the high and low sides of the resistor potential divider have different L/R ratios, the voltage division at the instant of flashover may be somewhat different than would be indicated by the resistance ratio alone. Thus, flashover voltages measured with such a divider may be somewhat in error, if only the resistance ratio is used in calculating the crest voltage.

Errors due to residual inductance in the divider elements become negligible when flashover occurs on the tail of the wave. As the applied voltage pulse passes through its crest value prior to flashover, the $L\,dI/dt$ component of voltage becomes very small, and hence, at crest voltage, the divider ratio is nearly equal to its resistance ratio. Thus, these crest voltages are accurately indicated.

In addition to amplitude errors caused by residual inductance in the potential divider, the presence of "hash" on the front of the oscillograms becomes increasingly annoying as the steepness of the wave increases, and the time to flashover becomes smaller and smaller. These extraneous signals obscure the start of the voltage wave and generally make measurements of time to flashover inaccurate and difficult. These same disturbances have little effect, when flashover occurs on the tail of the wave since they are generally gone long before crest voltage is reached.

The primary purpose of the doubly shielded isolated screen room which now houses the cathode-ray oscillograph (CRO) in the High Voltage Laboratory of The Ohio Brass Company at Barberton, Ohio, is to eliminate these extraneous signals.

The Isolated Screen Room Installation

The ideal place to locate the transient deflection plates of the CRO would be right across the low side of the potential divider with leads approaching zero in length. Since this location is generally quite impractical, the next best thing is to provide a circuit which will faithfully reproduce across the transient plates of the CRO the voltage which appears across the low side of the potential divider, without introducing any extraneous voltages from any other source. It is believed that the doubly shielded isolated screen room about to be described meets this requirement.

The principal elements of this installation, as shown in Fig. 1, include the impulse generator, the wave-forming network, the test specimen, the potential divider, the triple-shielded coaxial transient cable, the doubly shielded screen room, the isolated power supply, and the light-pulse trigger circuit.

The Impulse Generator

The impulse generator employs the conventional Marx circuit wherein the capacitors are charged in parallel and discharged in series. In this particular generator one side of the capacitor bank is charged during one half-cycle and the other side is charged during the alternate half-cycle, with R_{13} serving as a return path to ground for both half-cycles of the charging period. Thus, when the generator is fully charged point A may be at plus 75 kv with respect to ground, point B is at minus 75 kv with respect to ground, and the ungrounded end of R_{13} is at ground potential, since there is no longer any charging current flowing through it.

The impulse generator is fired by a discharge through the 3-ball gap, G_3 which is connected between point A and the common ground. Firing of G_3 causes point A to fall from plus 75 kv to ground potential. Because of the charge on the first two capacitors of the impulse generator, point B falls from minus 75 kv to minus 150 kv with respect to ground.

Since point D is momentarily held at its initial potential of plus 75 kv by the charge on the stabilizing capacitor C_6, the potential across the first series gap G_4 is suddenly increased from 150 kv to 225 kv. This causes gap G_4 to flash over, and thus connect point D to point B by a low impedance path.

The potential of point D then falls quickly from its initial value of plus 75 kv to minus 150 kv with respect to ground. This in turn places an excessive voltage across the second series gap, and the discharge process proceeds up the generator, eventually causing all series gaps to flash over and thus connect all capacitors of the generator in series.

Wave-Forming Network

The purpose of the wave-forming network is to control the shape of the wave applied to the test specimen. In the case about to be described, it was desired to apply a linearly rising wave to the test specimen, and to vary the rate of rise of this wave over a rather wide range of values. The connections and the range of magnitudes of controlling elements used in this particular investigation are shown in Fig. 1. The internal series resistance of the impulse generator is also considered to be a part of the wave-forming network, and was varied from 0 to 300 ohms during these tests. All resistances used in the wave-forming network are noninductive wire-wound units.

The Test Specimen

As shown in Fig. 1 the test specimen was a 12.5-cm (centimeter) sphere gap with a 6-cm spacing. This test specimen was chosen in order to demonstrate the effectiveness of the screen room and special potential divider by comparing test results with those obtained by Park and Cones[1] on a similar specimen using a similar potential divider at the National Bureau of Standards.

Paper 58-18, recommended by the AIEE Special Instruments and Auxiliary Apparatus Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 3-7, 1958. Manuscript submitted October 15, 1957; made available for printing October 28, 1957.

Fig. 1. The isolated screen room installation for the measurement of steep-front impulse waves

The common ground for the entire impulse circuit is at the base of the test specimen. The firing gap G_3 of the impulse generator is connected to this common ground. This method of ground keeps the main discharge currents out of the laboratory grounding grid and hence reduces differences in potential which might otherwise occur at different points in the grid if high level steep-front currents were intentionally introduced therein.

Even though a single common ground is used for the main impulse currents, there are charging currents which flow through the stray capacitances that exist between the laboratory ground grid and high-voltage portions of the impulse generator and its associated circuits. These charging currents flowing in the ground grid towards the single common ground point may produce sizeable potentials between different points in the grid, especially when they are produced by extreme steep-front voltage pulses.

The Potential Divider

The potential divider used in this investigation was patterned after the one described by Park and Cones.[1] Fig. 2 shows the divider connected across the 12.5-cm sphere gap with a 6-cm spacing. The top of the grounded sphere is approximately 13 inches above the rail which is intimately bonded to the laboratory ground grid. The point on the rail directly below the sphere is the common ground for all the impulse circuits. The ground connection of the potential divider and the ground lead from gap G_3 of the impulse generator are returned to a point just below the lower sphere, and just above the common ground point.

The high-voltage side of the potential divider R_1 has a resistance of about 1,000 ohms, and consists of ten 100-ohm Karma (Karma is the trade name for nickel-chromium-aluminum-iron alloy having a high resistivity and a low temperature coefficient of resistance) resistor units similar to those described by Park and Cones.[1] The over-all length of the divider is slightly over 50 inches.

Individual elements of the high-side divider are shown in Fig. 3. Each unit is made on a 1/2-inch-diameter polystyrene rod and is about 5 inches over-all length. A 3/8-inch-long brass ferrule at each end provides convenient terminals.

The resisitive element consists of two insulated and oppositely wound layers of Karma ribbon, 1/32 inch wide and 0.001 inch thick, separated by a double thickness of 0.001 inch thick by 0.50 inch wide Mylar (Mylar is the trade name for polyester insulating material) tape wound with half overlap. The second layer of Karma ribbon is also covered with Mylar tape to protect the winding while handling the units.

The low-voltage side of the potential divider R_2 has a resistance of about one ohm. This value was chosen so as to give the over-all divider a ratio of about 1,000 to 1, which provides a convenient magnitude of voltage on the plates of the CRO.

A close-up view of R_2 with the high side resistor R_1 connected to the line terminal and the triple shielded coaxial cable connected to the output terminal is shown in Fig. 4, with the shield removed. The purpose of the shield, which is shown in place in Fig. 2, is to prevent the possibility of any stray capacitance coupling between the junction of R_1 and R_2 and any external high-voltage circuit. With the shield in place the only current that can flow in R_2 is that which is conductively supplied to it through R_1.

Details of the construction of R_2 are shown in Fig. 5. The resistive element consists of four parallel loops of Karma ribbon, 1/16 inch wide by 0.001 inch thick, arranged 90 degrees apart about

the axis of the resistor. Each loop is arranged to double back on itself with a single layer of 0.001-inch-thick Mylar ribbon between the two sides of the loop. The ends of each loop are carefully soldered to circular electrodes. The four loops are firmly pressed between two clamping plates of insulating material. A standard coaxial terminal provides a convenient means for connecting to the high side of the 1-ohm resistor. Its center terminal is connected to the upper electrode by a contact screw. The upper electrode in turn is connected to the line terminal with four screws in parallel which provides a current path symmetrical about the axis of the unit. The lower electrode is intimately connected to the flange of the coaxial terminal which is connected to the base plate, which in turn is connected to the ground terminal. This construction provides a one-ohm resistor unit which has a very low inductance, and a convenient means for connecting to a coaxial cable.

THE TRIPLE-SHIELDED COAXIAL CABLE

The transient cable is basically an *RG-11/U* type with a surge impedance of 75 ohms. It is available commercially with a second outer shield insulated from the first shield, and also covered with an insulating jacket. A third shield was added by pulling a hollow braided sheath over the doubly shielded cable. A plastic coat was then pulled over the third shield, primarily for its mechanical protection.

The input end of the triple-shielded cable was fitted with a standard coaxial terminal. All three shields were bonded together at this connection as shown in Fig. 1.

THE DOUBLY SHIELDED SCREEN ROOM

The doubly shielded screen room, which is permanently located in the control room just off the main laboratory floor is shown in Fig. 6. While the control room is not completely electrostatically shielded from the field of the impulse generator, it does provide some degree of shielding for equipment and personnel.

The screen room is mounted on porcelain insulators so that it may be completely isolated from any ground connections in the control room.

As shown in Fig. 1, the outer screen is connected to the outer shield on the transient cable, the inner shield is connected to the middle shield on the transient cable while the CRO cabinet inside the screen room is connected to the inner shield of the transient cable. Thus, the CRO cabinet, the inner screen room, and the outer screen room form a series of three concentric Faraday cages within the innermost of which are located the transient plates of the CRO. The only common connection between the three concentric cages is located at the input end of the transient cable.

THE CRO

The CRO used in this investigation is a commercially available hot cathode type, which comes complete with sweep circuits, delay circuits, timing circuits, calibrating circuits, and all necessary power supplies for operation of all of these circuits. It is shown in Fig. 7 as it is normally used in the screen room.

For this investigation it was found that a very careful termination of the

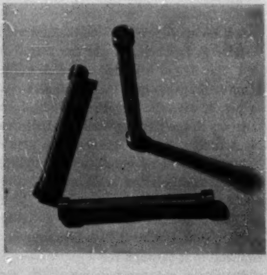

Fig. 3. A number of 100-ohm high-side divider resistor units showing the ferrule-type construction. Ten of these units are connected in series to make the 1,000-ohm high-side resistor, R_1

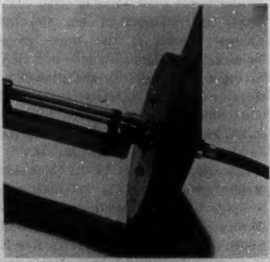

Fig. 4. Low side resistor R_2 with shield removed to show line terminal clip for connection to the high side resistor R_1. The four parallel resistance elements of R_2 are clamped between the two insulating plates which are shown to the left of the brass base plate

transient cable in its surge impedance is essential for successful operation with steep-front impulse waves. For this purpose a special low-inductance 75-ohm resistor R_3 was made by compressing in a zigzag fashion a suitable length of Karma ribbon with two layers of 0.001-inch Mylar tape between adjacent layers. In these tests the transient plates of the CRO were connected directly across the output end of the coaxial cable and its terminating resistor R_3.

SCREEN ROOM POWER SUPPLY

Since the interior of the screen room must be completely isolated from ground, it is essential that power for the CRO and other devices used therein be provided with a source which is completely isolated from ground. For this purpose a motor-generator set is used, with the motor located outside the screen room and the generator inside the inner screen. Complete isolation is provided by coupling the two units with an insulating shaft which extends through the walls of the screen room. The motor of this power supply is shown in Fig. 6 with its insulating shaft extending into the screen room.

SYNCHRONIZATION

In order to obtain suitable oscillograms of a transient phenomenon, it is necessary to provide a suitable sweep pulse on the horizontal plates of the CRO. Furthermore, it is essential that this sweep pulse be properly synchronized with the arrival of the transient pulse at its vertical plates. There are various methods for accomplishing this synchronization, all of which require a signal from somewhere in the system.

It is possible to bring an electric synchronizing pulse from a number of points in the impulse circuit, but all of these methods require the introduction of a second transient cable into the inner shielded cage of the CRO. This may lead to the introduction of spurious responses in the oscillograms.

LIGHT-PULSE SYNCHRONIZATION

In order to avoid the necessity of bringing a second transient cable into the screen room, a light-pulse synchronizing signal is used. This pulse of light, which travels readily through the walls of the screen room, cannot possibly introduce extraneous voltages inside the shielded cage.

The basic elements of the system are shown in Fig. 1. In the trigger circuit, equal capacitors C_1 and C_2 in series are charged to the same potential as the first capacitor in the impulse generator. Hence, point E in the trigger circuit has the same potential as point A during the charging period. The potential of point F is thus always at one-half the potential of point E with respect to ground.

Equal capacitors C_3 and C_4 are connected to C_1 and C_2 by two 2-megohm resistors. Hence, the potentials of points E' and F' are approximately at the potentials of points E and F respectively, since the time constants affecting the charging of C_3 and C_4 are short compared to the charging time of the impulse generator.

The middle sphere of the impulse generator tripping gap G_3 is connected to the point F' through a 20,000-ohm resistor R_{14}, a short connecting cable, a 1-μsec delay cable and an 11-ohm resistor R_{11}. Since practically no current flows through this path during the charging period, the middle sphere of gap G_3 is at the potential of point F' which in turn is approximately midway in potential between point E' and ground. Hence this middle sphere is approximately at one-half the potential of point A during the charging period and the gap G_3 does not flash over.

After the impulse generator is charged to the desired potential, the firing solenoid is energized and the midball of the firing gap G_1 is lifted mechanically. This causes gap G_1 to flash over, thereby permitting capacitor C_4 to discharge through R_{11}, gap G_1, and the 2,000-ohm resistor R_{12}. The rapid rise in potential across R_{12} causes the CRO synchronizing gap G_2 to flash over. Following this, capacitor C_4 discharges rapidly through R_{11}, and gaps G_1 and G_2.

After gap G_2 fires, point H falls rapidly to near zero potential, with R_{11} consuming most of the voltage still remaining on C_4. This drop in potential at point H is communicated after a one-μsec delay to the middle sphere of gap G_3. This causes G_3' to flash over and current to flow through R_{14}. Because of its high resistance, a small current through R_{14} causes the potential of the middle sphere to rise rapidly and thus impress the potential of point A across the lower portion of gap G_3. This causes G_3'' to flash over, and

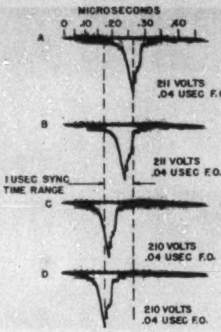

Fig. 8. Voltage oscillograms on a 12.5-cm sphere gap with 6-cm spacing with all connections as in Fig. 1, which includes the use of a light pulse for synchronization

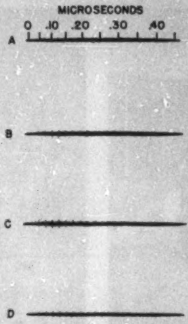

Fig. 9. Zero line oscillograms obtained with same conditions as those for Fig. 8, except lower end of R_1 is connected directly to ground terminal of R_2

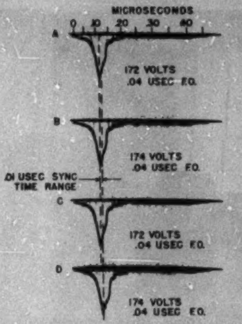

Fig. 11. Voltage oscillograms obtained with conditions same as those for Fig. 8, except a delay cable is used for synchronization

now since both G_3' and G_3'' are conducting, point A becomes connected to the common ground, and the impulse generator is discharged, as described in the preceding.

The flashover of gap G_2 produces a pulse of light which travels through the walls of the screen room to an electron multiplier phototube. A pair of condensing lenses focuses the arc in gap G_2 onto the phototube, thereby insuring a strong signal.

The output signal of the phototube passes through suitable amplifiers into the 0–15-μsec delay circuit which is provided in the CRO. The output of the delay circuit is introduced into the sweep circuit, where it triggers the sweep pulse.

In the circuit just described, the electric pulse created by the firing of G_2 initiates a train of events that ultimately culminates in the arrival of a transient signal at the vertical plates of the CRO. The light pulse, which is created simultaneously with the electric pulse, initiates a second train of events which ultimately culminates in the arrival of a sweep signal at the horizontal plates of the CRO. Suitable synchronization is effected when the sweep signal arrives at its plates just far enough ahead of the transient signal to establish a short zero line. Practically, synchronization is effected by suitable adjustment of the 0–15-μsec delay provided in the CRO.

Performance of the Installation

The performance of the over-all installation can be illustrated by comparing oscillograms taken under different conditions, with the same transient being applied, which in this case is the negative polarity 0.04-μsec flashover of a 12.5-cm sphere gap with a 6-cm spacing.

The four oscillograms shown in Fig. 8 are successive impulse shots applied to the test specimen. The freedom from "hash" on the front of the wave and the linear rise to flashover indicate the excellent results that may be obtained in the doubly shielded isolated screen room. This result is further emphasized by the lack of disturbances in the zero line oscillograms shown in Fig. 9 which were taken with the lower end of the high-voltage divider resistor R_1 connected to the ground terminal of R_2 rather than to its line terminal. The synchronization was the same for the oscillograms of both Figs. 8 and 9. If extraneous disturbances were present, this test would certainly reveal them.

Synchronization with the light pulse method appears to vary not more than 0.1 μsec for a series of repetitive shots as is shown by the four oscillograms in Fig. 8. This means that the two trains of events that are initiated by the firing of gap G_2 must be repetitive within this time interval.

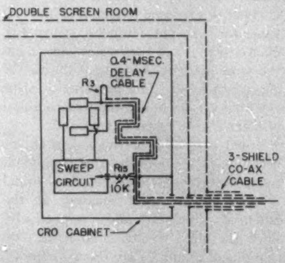

Fig. 10. Details of CRO synchronization using a delay cable

Delay Cable Synchronization

The use of a delay cable gives a method of synchronization which does not require a second incoming signal. As shown in Fig. 10, the incoming transient is used to trigger the sweep circuit, through a 10,000-ohm noninductive resistance tap at the end of the triple-shielded coaxial cable. The incoming signal must travel for an additional 0.4 μsec before it comes to the transient plates of the CRO. This delay provides sufficient time to get the sweep pulse started and thus provides synchronization.

Oscillograms obtained with delay cable synchronization are shown in Fig. 11. The results are equally as good as those obtained with light pulse synchronization shown in Fig. 8, but the amplitude is reduced from 210–211 volts to 172–174 volts, even though the magnitude at the source of these pulses is practically the same. The 18% loss in amplitude is due to attenuation in the 0.4 μsec delay cable. This means that if the delay cable were to be used for synchronization, a rather large correction factor would have to be used to compensate for cable attenuation, which could easily lead to inaccuracies. For this reason the delay cable method of synchronization does not appear as feasible as does the light pulse method.

Electric Pulse Synchronization

An external electric pulse may be brought into the screen room using

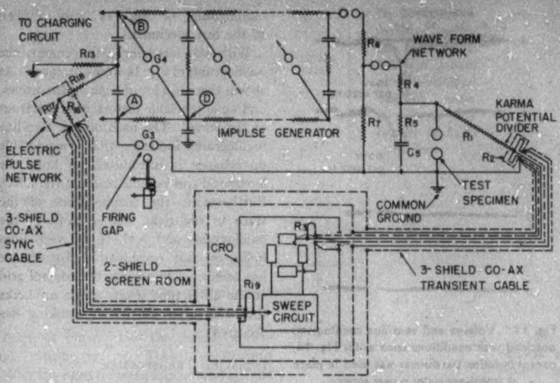

Fig. 12. Synchronization of CRO with electric pulse from impulse generator

a second triple-shielded cable. The diagram in Fig. 12 shows the details of one such method that was investigated.

The pulse is obtained from a potential divider network connected between the midpoint of the first capacitor bank of the impulse geneator and ground. While this point is practically at ground potential during the charging period, it suddenly jumps to minus 75 kv the instant gap G_3 is fired. A small fraction of this pulse, the magnitude of which is determined by the electric pulse network, is brought into the sweep circuit through a triple-shielded cable, which is terminated with a 75-ohm noninductive resistor R_{19}. The delay in breakdown of gap G_4 provides a suitable time lag between the starting of the sweep and the firing of the generator to accomplish synchronization.

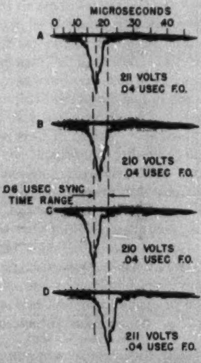

Fig. 13. Voltage oscillograms obtained with conditions same as those for Fig. 8, except an electric pulse is used for synchronization

In spite of the care used in shielding the cable and the input network, extraneous signals are introduced into the oscillograms as shown in Fig. 13. The source of these voltage oscillograms is the same as for the oscillograms of Fig. 8, and the amplitudes are about equal. However, there are superimposed oscillations on the front of the waves in Fig. 13 that are not present in Fig. 8. Apparently, these oscillations are caused by spurious signals, which are superimposed upon the sweep circuit rather than upon the transient plates. Here again the superior performance of the light pulse synchronization method is apparent.

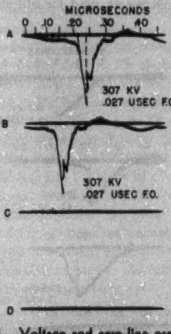

Fig. 14. Voltage and zero-line oscillograms on a 12.5-cm sphere gap with 6-cm spacing, with all connections as in Fig. 1 which includes screen room isolated from reference ground in control room. Zero-line oscillograms were obtained immediately following voltage oscillograms, but with lower end of R_1 connected directly to ground terminal of R_2. The same settings of the synchronization controls were used

Effect of Grounding Outer Screen Room in Control Room

When the impulse generator is fired, appreciable space charging currents may flow in the stray capacitances that inherently exist between the laboratory ground grid and the high voltage portions of the impulse generator and associated high-voltage circuits. Since all of the space currents that are intercepted by the ground grid must return through this grid to the common ground point at the base of the test specimen, it is possible that this common ground point may be raised in potential with respect to a reference ground which is outside the electrostatic field of the impulse generator.

When the screen room is connected only to the common ground at the base of the test specimen, as is shown in Fig. 1, it is possible for an appreciable difference in potential to exist between the screen room and grounded objects in the control room which are more or less shielded from the electrostatic field of the impulse generator. Oscillographic measurements show that peak voltages in the order of 35 kv exist between the screen room and the reference ground in the control room, when a very steep-front impulse voltage is applied to the 12.5-cm sphere gap with 6-cm spacing. While this pulse is of short duration, it does constitute a hazard to personnel in the control room, and it would be desirable to eliminate it, if it is possible to do so without affecting the resulting oscillograms.

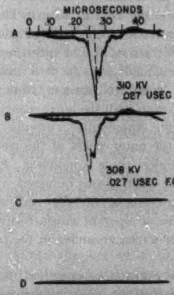

Fig. 15. Voltage and zero-line oscillograms obtained with conditions same as for Fig. 14, except outer shield is connected to reference ground in control room

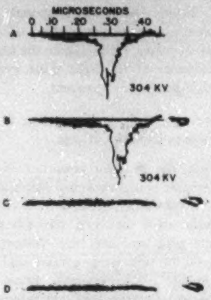

Fig. 16. Voltage and zero-line oscillograms obtained with conditions same as for Fig. 14, except oscillograph was placed outside of screen room and all three shields were connected to reference ground in control room

To investigate this possibility two sets of oscillograms were taken with identical pulses applied to the test specimen. The first set of oscillograms is shown in Fig. 14, which shows the results when the impulse generator, charged to 1,400 kv, is discharged into the test specimen. As shown, a crest potential of 307 kv is attained, and flashover occurred at 0.027 μsec. The front of the wave is practically linear and there is no hash at the start of the wave. The screen room is isolated, and synchronization is by light pulse. The two zero lines in Fig. 14 were made with R_1 connected to the ground terminal of R_2, thus bypassing the 1-ohm resistor R_2. There are no disturbances on the zero line, indicating complete freedom from stray pick-up.

The oscillograms shown in Fig. 15 were made under conditions identical to those of Fig. 14, except that the outer screen room was connected to the reference ground in the control room. The two flashover oscillograms are identical to those obtained in Fig. 14 with the screen room grounded, and the two zero lines indicate complete freedom from stray pick-up, even with the outer screen room grounded. Apparently, currents which flow in the outer shield of the transient cable under these conditions do not effect the oscillograms obtained. Thus, in the interests of safety to personnel, it is possible to operate satisfactorily with the outer screen grounded in the control room.

In the event it is suspected that the grounding of the outer screen room is influencing the oscillograms it is possible to take a set under both grounded and ungrounded conditions for checking this point. For this reason, it is believed desirable to maintain insulators under the screen room, so that this point may be checked occasionally.

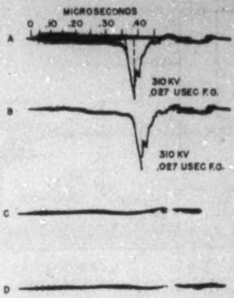

Fig. 17. Voltage and zero-line oscillograms obtained with conditions same as for Fig. 14, except isolation transformer was used in place of motor-generator power supply

CRO Removed from Screen Room

To emphasize the need for operating inside the screen room, the CRO was temporarily removed and placed on the floor just outside the screen room. The inner shield and central conductor of the triple-shielded cable were extended through the open door to the CRO and both this shield and the cabinet were grounded. The isolated power supply and light-pulse synchronization were used. The same steep-front impulse waves that were used for obtaining the oscillograms of Fig. 14 were applied to the test specimen.

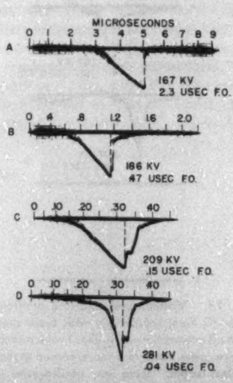

Fig. 18. Typical voltage oscillograms from steep-front tests on a 12.5-cm sphere gap with 6-cm spacing, using the installation described in Fig. 1. Volt-time data from these oscillograms are included in Fig. 21

With the foregoing arrangement, the oscillograms of Fig. 16 were obtained. As shown there is a lot of hash on the waves, and an appreciable distortion of the front of the wave. The hash on the zero-line oscillograms indicates that considerable disturbance is introduced on both the horizontal and vertical plates of the CRO. Furthermore, the reappearance of the trace to the right side of both of the oscillograms and both of the zero lines indicates that considerable disturbance has been introduced into the control grid of the CRO tube itself, which unblanks the beam after the initial blanking has occurred.

Isolating Transformer

To evaluate the advantage of the isolated power supply in the screen room, a test was made wherein all power to the screen room was supplied through a commercial isolating transformer instead of the motor-generator set. For this test, the CRO cabinet and both inner and outer screen rooms were connected to the reference ground in the control room. The test voltage applied to the specimen was the same as that used in obtaining the oscillograms of Fig. 14.

The results of this test are shown in Fig. 17. While the disturbances introduced by this isolating transformer are not as severe as those shown in Fig. 16, they do produce some disturbances which are particularly noticeable on the zero-line oscillograms. Unblanking of the

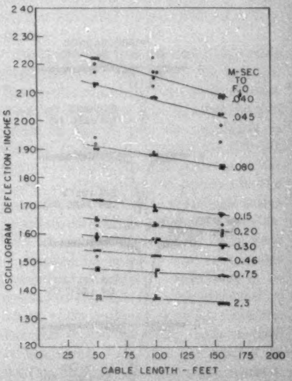

Fig. 19. Attenuation characteristics of triple-shielded transient cables of different lengths for voltages rising linearly to flashover at times indicated

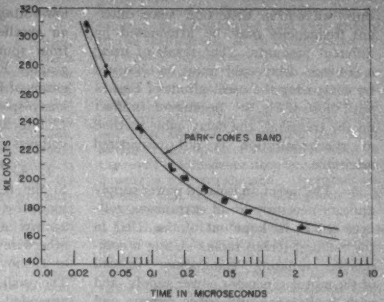

Fig. 21. The comparison of volt-time data for a 12.5-cm sphere gap with 6-cm spacing with negative polarity linearly rising voltage pulses applied to upper sphere, with a band obtained by Park and Cones on a similar test specimen. All voltages shown have been corrected to 25 degrees centigrade and 760 mm Hg

beam at the right of the oscillograms is also quite severe. These oscillograms show the need for complete isolation of the power supply as provided by the motor-generator set.

Correlation with National Bureau of Standards

To demonstrate the over-all performance of the complete installation as shown in Fig. 1, which includes the doubly shielded screen room, isolated power supply, light-pulse synchronization, triple-shielded transient cable, and Karma resistance divider, the volt-time curve of a 12.5-cm sphere gap with a 6-cm spacing was run with linearly rising voltages which produce flashovers in the time range of 0.027 to 2.3 μsec.

Typical oscillograms obtained during this series of tests are shown in Fig. 18 for times to flashover of 2.3, 0.47, 0.15, and 0.04 μsec. The corresponding oscillogram for a time to flashover of 0.027 μsec is shown in Fig. 14. As shown in all of these oscillograms, the fronts of these waves are practically linear clear up to the instant of flashover. The time to flashover was determined by extrapolating the slope of the upper half of the oscillogram back to the zero line.

The crest value was determined by scaling the maximum deflection on each oscillogram. Each deflection was then multiplied by the voltage sensitivity of the CRO tube, the attenuation correction factor of the triple-shielded 100-foot coaxial transient cable, the ratio of the Karma resistance divider, and finally the air density correction factor, to obtain the actual flashover voltage at standard atmospheric conditions.

ATTENUATION CORRECTION FACTOR OF TRANSIENT CABLE

Since the attenuation characteristics of the transient cable are undoubtedly different for waves of different steepness an investigation was made using three different lengths of cable for a number of different wave fronts. The results of this test, using cables of 50, 100, and 156 feet, are shown in Fig. 19. For each wave front, identical voltage waves were applied to the test specimen for each cable length. Hence, differences in oscillogram deflections are due only to the differences in attenuation in the different length cable. The repetitive nature of the pulses applied to the test specimen is indicated by the closeness of the plotted data points for a given cable length and steepness of wave.

As indicated in Fig. 19, straight lines with increasing slope at the shorter times to flashover fit the data quite well. From the slope of the line, the correction factor for a 100-foot cable may be determined. The curve shown in Fig. 20 gives this correction factor in terms of the time to flashover, and the slope of each line in Fig. 19 matches this curve for the appropriate time to flashover. Note that the curve of Fig. 20 becomes asymptotic to a horizontal line which corresponds to the d-c correction factor for the cable, based upon its resistance only.

CORRELATION WITH PARK AND CONES

Crest values of voltage, obtained by multiplying the oscillogram deflection by the sensitivity factor of the CRO tube, the cable attenuation correction factor from Fig. 20, the multiplying ratio of the Karma resistance divider, and the air density correction factor, are plotted in Fig. 21. Also plotted in this figure is the band given in Fig. 5 of the Park-Cones' paper from the National Bureau of Standards. As shown, there is an excellent correlation between results obtained using the equipment described in this paper and those reported by Park and Cones.[1]

Conclusions

1. The doubly shielded isolated screen room installation, including the triple-shielded transient cable, isolated power supply, and light-pulse synchronization, does an excellent job in preventing the occurrence of spurious response in the CRO.

2. One outstanding advantage of the light-pulse synchronization method is the complete freedom from extraneous voltages within the screen room. The effects of extraneous voltages that may be unintentionally introduced into the oscillograph, even with a carefully design circuit such as is shown in Fig. 12, are clearly indicated in the oscillograms of Fig. 13.

3. A second advantage of the light pulse synchronization method is the ease with which the transient may be positioned with respect to the sweep circuit, thus permitting it to be recorded in the most favorable position on the CRO screen.

4. While the use of a delay cable within the isolated screen room can provide synchronization without the introduction of a second signal, the 250-foot length required for satisfactory synchronization introduces considerable attenuation of the main crest and may also intro-

duce wave-form distortion since different frequencies may be attenuated by different amounts. The result of using a 0.4-μsec delay cable may be observed by comparing the oscillograms of Fig. 11 with those of Fig. 8. Because of its effect on the transient, the delay cable method of synchronization is not considered advisable.

5. The use of an isolated power supply appears necessary if all extraneous voltages are to be kept out of the CRO in the isolated screen room. Using a commercial isolating transformer instead of the motor-generator power supply, and with both inner and outer screens and CRO cabinet connected to the reference ground in the control room, the oscillograms of Fig. 17 were obtained. The presence of spurious responses, particularly of the zero-line oscillograms, indicates the unsatisfactory performance that may result if a completely isolated power supply is not used.

6. Zero-line oscillograms, which are taken when the lower end of the high-voltage divider resistor R_1 bypasses the low-voltage divider resistor R_2, provide an excellent indication of the freedom from spurious responses in the oscillograph. For example, the zero-line oscillograms of Fig. 9 show practically no spurious responses, while those in Figs. 16 and 17 indicate that appreciable extraneous voltages are present.

7. Connecting the outer screen room to the reference ground in the control room for the protection of personnel against high voltage pulses, which would otherwise exist momentarily at the instant of flashover, appears to be permissible. The oscillograms of Fig. 15, taken with it grounded, compare favorably with those of Fig. 14, taken with it isolated. In any event, as long as the insulators are kept under the screen room, it is possible to make such a check at intervals when other types of testing may be in progress.

8. The Karma resistance divider, which is described in this paper, appears to be quite satisfactory for steep-front impulse testing. This conclusion is based upon the excellent correlation obtained between the volt-time data on a 12.5-cm sphere gap with a 6-cm spacing and the corresponding data for the same test specimen, as presented by Park and Cones.[1]

9. The design of the 1-ohm low-side resistor R_2, as described in this paper appears to be quite satisfactory. The shield, which protects the line terminal from external stray capacitances, appears to be quite effective. This fact is shown by the zero-line oscillograms of Fig. 8, which were obtained when the high-side resistor R_1 bypassed the low-side resistor R_2 with the transient cable still connected to it.

10. The excellent correlation obtained with Park-Cones' data indicates the practicability of using the volt-time curve of a sphere gap as a reference standard for checking voltage dividers intended for steep-front measurements, as proposed by those authors.

Discussion

J. H. Park (National Bureau of Standards, Washington, D. C.): It is indeed gratifying when experimental results obtained independently in two laboratories agree almost perfectly as indicated by Fig. 21 in this paper. This is especially significant since agreement is obtained for the sparkover voltage of sphere gaps at times to sparkover down to 0.04 μsec. It definitely indicates the feasibility of using sphere-gap volt-time curves as reference standards for checking the accuracy of steep-front measurements.

However, before this curve can be accepted as part of a standard, one discrepancy must be resolved. As stated in the discusser's paper,[1] it would be expected that very slow rates of voltage rise would correspond to full wave sparkover so that for longer times to sparkover the volt-time curve should level off at the full wave sparkover value. At present this curve appears to be leveling off at about 150 kv which is 4.5% higher than the full wave value given in AIEE Standard No. 4 (143.5 kv). Data obtained last summer at the National Bureau of Standards (NBS) yielded a full wave sparkover value of 148 kv. Since this is very close to the minimum of the volt-time curve (as obtained both at NBS and Ohio Brass Company) it is suggested now that possibly the value given in AIEE Standard No. 4 is not correct for 12.5-cm spheres spaced 6 cm apart. As a check on full-wave measurements made at the NBS, data were also obtained on 25-cm-diameter spheres spaced 6 cm apart, giving a full wave 50% flashover voltage of 159 kv which agrees with the value obtained from Standard No. 4 to within 1 per cent.

The extreme shielding precautions found to be required at the Ohio Brass Laboratory indicate the importance of checking for stray pickup errors by the methods described in this paper. Of course it need not be concluded that such extreme shielding precautions must be taken at all laboratories. A continuously evacuated oscillograph whose deflecting system is inside a thick-wall iron cylinder, directly connected to the laboratory floor, would inherently have better shielding than a sealed glass envelope tube. An oscillograph with lower sensitivity would require a higher voltage from the divider low side and this tends to swamp out any pickup voltage. Also, the details of the exact method used to connect the center conductor and sheath of the measuring cable both at the divider low side and at the oscillograph are extremely important in eliminating pickup from ground currents. By making use of these factors, pickup troubles are practically eliminated at the NBS without resorting to double shielding of oscillograph and cable or isolation of power supply.

A. F. Rohlfs, J. Kresge, and **F. A. Fisher** (General Electric Company, Pittsfield, Mass.): This paper clearly illustrates the type of disturbances that may be encountered when attempting to measure short-duration, high-voltage impulse waves. It is interesting to note that the oscillograms show the signal to be measured with the correct amplitude even for those conditions where the wave shape is disturbed very badly. Evidently the disturbances were in the horizontal sweep circuits of the oscilloscope, rather than in the vertical deflection system. This is not too surprising since the horizontal sweep generator would have an output impedance much higher than the 75-ohm impedance level of the vertical deflection system.

We have encountered the same sort of problems and have observed sweep distortion phenomena very similar to those shown in the paper. Our approach toward eliminating such disturbances has been along two distinct lines. One has been to improve the grounding circuitry; the other has been to improve the oscilloscope circuitry so that it is less susceptible to external disturbances. This has been done by lowering the impedance of the horizontal sweep generator, isolating the vertical and horizontal deflection systems as much as possible and balancing the residual capacitances between the horizontal and vertical deflection systems. So far these approaches have been adequate.

There can be no question about the effectiveness of using the doubly shielded room, light-pulse synchronization, and isolated power supply. However, the question of personnel safety must be faced and in our judgment it requires that the oscilloscope chassis be grounded directly to the shielded room in which it is placed. If the oscilloscope were grounded in this manner, we wonder how much improvement could have been obtained if only the horizontal sweep circuit had been worked on?

There appears to be one apparent discrepancy between the caption for Fig. 17 and the body of the paper. The caption states that all conditions were the same as those for Fig. 14 except that the motor-generator supply was replaced by an isolation transformer. In the body of the paper it is stated that during the tests with an isolation transformer the inner and outer screened rooms were connected to the control room ground. If this is true then can any rigorous conclusion be drawn about the effectiveness of an isolation transformer when grounding of the inner and outer screened rooms may have had a detrimental effect in itself? Have the authors made tests using an isolation transformer but with the inner and outer screened rooms isolated from the control room ground and if so would they comment on the results?

C. J. Miller, Jr. and J. F. Wittibschlager: Mr. Park suggests the possibility that the negative flashover voltage of 143.5 kv for a 6-cm gap between 12.5-cm spheres, as now given in AIEE Standard No. 4, may be somewhat in error, since the volt-time curve which he obtained with impulse waves having a linearly-rising front levels off at about 150 kv at longer times to flashover. This possibility is further increased by observing a negative critical flashover voltage of 148 kv for this same gap, using the conventional $1^1/_2 \times 40$-μsec wave.

In order to check this value, a critical flashover test was run in Barberton, using a conventional $1^1/_2 \times 40$-microsecond wave on the 6-cm gap spacing and arrangement shown in Fig. 2. The results of this test gave a negative critical flashover value of 148.5 kv, which agrees very well with Mr. Park's test value of 148 kv. Thus, it would appear that the value of 143.5 kv given in AIEE Standard No. 4 is somewhat low. As a check on the accuracy of voltage measurement, a positive critical flashover value of 152 kv was obtained at the same time, and this value agrees quite well with the 153.8-kv value given in AIEE Standard No. 4. It would thus appear that the discrepancy indicated by Mr. Park may now be confirmed. However, confirmation from a third laboratory is highly desirable.

Messrs. Rohlfs, Kresge, and Fisher indicate that they, too, have encountered extraneous voltages in the horizontal sweep circuit which disturb the wave shape in a manner similar to that shown in the paper, and that they have been able to eliminate such disturbances by improving the grounding circuitry and the oscillograph circuitry. Such an approach appears to be impractical when using a commercially available hot-cathode type of oscillograph because of the intricate electronic circuits involved. It became a much simpler problem just to prevent the disturbances from ever getting to the oscillograph, as is accomplished by the doubly-shielded screen room.

As to personnel safety, the oscillograph chassis and the inner screen room are bonded together at the input end of the transient cable. The only potential which can exist between the chassis and inner screen at the operator's position would be the result of impedance drop due to currents flowing in the two sheaths. Operating experience has shown that this potential is negligibly small.

In running the test with an isolation transformer, the results of which are shown by the oscillograms in Fig. 17, it was necessary to ground the screen room to the control room ground to prevent flashover from the primary to secondary winding. Tests, which are not included in the paper, were also made for this same condition, except that the motor-generator power supply was used. These oscillograms show freedom from the disturbances obtained with the isolation transformer. Hence, it may be concluded that the disturbances shown in Fig. 17 are introduced through the isolation transformer and are not due to the inner and outer screen rooms and the CRO cabinet being connected to the control room ground.

Analysis of Nonresonant Charging Circuit for Magnetic Pulse Generator

N. L. WEINBERG
NONMEMBER AIEE

THE USE of saturable reactors to produce narrow, high-energy pulses is becoming increasingly important in radar and similar applications where rugged devices of high reliability are required. General principles of operation of these magnetic pulse generators are discussed thoroughly in the original paper on this subject by W. S. Melville.[1] Subsequently, other articles have been published dealing with design criteria, core volume derivations, and other additions to the theory of operation and state of the art.[2–5] These works, however, concern themselves mainly with resonant charging circuits. The intent of this paper is to derive the fundamental equations for nonresonant operation of the input charging circuit and to compare performance as a function of the ratio of charging circuit frequency to line frequency. Piecewise linear analysis is the method employed to obtain the solutions of this nonlinear circuit.

The two most popular basic configurations are illustrated in Fig. 1 (the series line in *A*, the shunt circuit in *B*). Both circuits have the same type of output and the analysis contained herein is valid for both circuits in the ideal case. In the remainder of this paper, however, the discussion will be restricted to the series line which is the most common application of this type of device. The two modes of operation are termed uni-cycle and bi-cycle, with uni-cycle defined as one unidirectional pulse per cycle of input frequency and bi-cycle defined as one positive and one negative pulse per input cycle. Uni-cycle is accomplished physically by biasing the first reactor so that it can saturate only in one direction.

A brief description of circuit operation includes first the line charging unit, L and C_1. In the resonant case the voltage across the capacitor (which equals the voltage across L_1 in the ideal case) has the waveform illustrated in Fig. 2 where both uni-cycle and bi-cycle modes are compared with the source voltage. When the voltage on capacitor C_1 reaches its peak, reactor L_1 saturates and C_1 discharges through the saturated inductance of L_1 charging C_2. When the voltage on C_2 reaches its peak, L_2 saturates and C_2 discharges into the succeeding capacitor C_3. This process continues until the final capacitor C_n discharges through the saturated inductance of the final reactor L_n into the load R. The reactors are designed to saturate when the peak voltage is reached, and the discharge frequency of each stage is determined by the saturated inductance of the reactor and the capacity of the discharge loop. In the ideal pulser as well as in many practical models, the capacitors of each stage (when referred to the same impedance level where interstage transformers are used) are equal. Thus the discharge frequency of each stage is solely a function of the reactor saturated inductance. The saturated inductance of the first reactor is very much smaller than the charging inductance L so that the discharge fre-

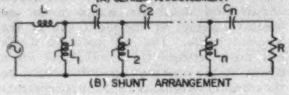
(A) SERIES ARRANGEMENT



(B) SHUNT ARRANGEMENT

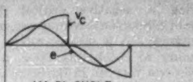
Fig. 1. Basic pulser circuits

quency of the first stage is greater than line frequency. The second capacitor, therefore, charges up faster than the first capacitor, resulting in a second-stage reactor with reduced turns-core area product and, consequently, reduced saturated inductance. The discharge frequency is thus increased over the first stage and pulse sharpening has been obtained. This process of pulse sharpening is continued until a sufficiently narrow pulse, as determined by load specifications, has been obtained in the final stage. Although indicated simply in the diagrams, for radar applications C_n could represent a pulse-forming network and R a pulse transformer driving a magnetron.

Reduction of size and weight of magnetic pulse generators (or pulsers as they are sometimes called) by core volume reduction is one of the major objectives in this field today. Increasing the pulse sharpening per stage cannot be achieved without using excessively large cores and for specifications on any given pulser, the optimum number of stages is easily determined. A reduction in the volume of the first stage without altering the pulse compression per stage would result obviously in a smaller pulser. Since the volume of the first-stage reactor is proportional to the volt-second integral (for given output pulse from first stage) of the waveshape on C_1, reduction in charging time keeping the peak voltage constant would result in a smaller reactor. By utilizing nonresonant charging, this can be accomplished and in the analyses that follow, the properties of the circuit relevant to pulser design will be derived for the ideal general case for both unicycle and bi-cycle modes.

Nomenclature

A = effective core cross-sectional area, square centimeters
ΔB = "knee-to-knee" flux density, gauss
C = capacitance of each stage, farads
e = instantaneous line voltage, volts
E = peak line voltage, volts
f = line frequency, cycles per second



(A) BI-CYCLE

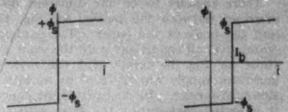
i = line current including both i_1 and i_2, amperes
i_1 = line current for reactor in saturation, amperes
i_2 = line current during capacitor charge, amperes
i_c = capacitor current, amperes
I_b = bias current referred to main winding, amperes
I_{bn} = normalized bias current, amperes
I_f = fundamental component of line current, rms, amperes
I_{rms} = root-mean-square value of line current, amperes
K = reactor turns-core area design factor
L = inductance of charging choke, henrys
L_{sk} = saturated inductance of kth reactor, henrys
$n = (w_0/w)$ = ratio of charging circuit frequency to line frequency
N = number of turns on reactor
P = pulser input power, watts
q = charge on C_1, coulombs
r = pulser repetition rate
t_0 = time at which reactor unsaturates
t_1 = zero crossover for uni-cycle capacitor voltage
v_c = instantaneous voltage on C_1, volts
V_c = peak voltage on C_1
ϕ = phase angle between line voltage and reactor saturation time
w = radian line frequency
$w_0 = (1/LC)^{1/2}$ = radian frequency of input charging circuit

Analysis of Bi-Cycle Mode

In the circuit simplifications that follow, ideal flux-current characteristics as shown in Fig. 3(A) will be assumed for all reactors. To facilitate discussion of the nonresonant case, typical waveforms of source voltage, line current, and capacitor voltage which could be obtained experimentally or by deduction are illustrated in Fig. 4(A). Zero time is chosen as the instant the reactor saturates. Since the phase angle between source voltage and firing point is a function of nonresonance, ϕ must be included in the analysis. All equations will be derived for the polarities illustrated and will be valid for $0 \leq wt \leq \pi$.

Immediately following discharge of capacitor C_1 at $t=0$, the reactors remain in saturation in the ideal case. Although this is not strictly true in actual modulators (since it takes a finite time for the pulse to travel down the chain until it is discharged into the load), the time is very small compared to the period of the input sinusoid. Therefore, the resulting error is negligible. The saturated inductances of the reactors are negligible impedances at line frequency as compared to the capacitor impedance so that during saturation, line current will flow through the reactors rather than the capacitors. In the final stage, load resistance is also negligibly small in comparison to capacitor impedance at line frequency so that the previous assumption is valid for the final stage as well. Since $L \gg L_{S1} \gg L_{S2} \dots \gg L_{SN}$, the impedance of this series chain of inductances can be represented by the charging inductance alone.

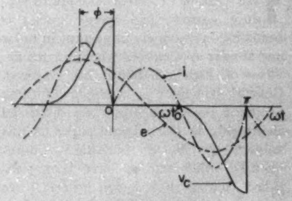
During unsaturation, the reactors are open circuits, since ideal characteristics are assumed, and the circuit becomes merely L and C in series. This assumption of zero exciting current is valid since this current is extremely small compared to circuit currents for the square-loop core materials employed in these pulsers.



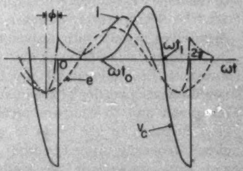
(A) IDEAL FLUX-CURRENT CURVE

(B) IDEAL FLUX-CURRENT CURVE FOR MAIN WINDING CURRENT UNI-CYCLE

Fig. 3. Magnetization curves



(A) BI-CYCLE



(B) UNI-CYCLE

Fig. 4. Waveforms

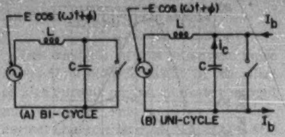


Fig. 5. Equivalent circuits

The equivalent circuit can thus be represented by the configuration shown in Fig. 5(A) with the switch symbolically indicating the two operating regions of the reactor.

Boundary conditions can be determined easily by deduction and confirmed by experiment. Optimum circuit operation requires that the reactor saturate when V_c has been reached. Thus $dv_c(0)/dt=0$ and since current is continuous through L (due to the requirement of continuous flux linkages),

$$i(0)=0 \tag{1}$$

Since the circuit must be periodic at line frequency,

$$i\left(\frac{\pi}{w}\right)=0 \tag{2}$$

At $t=t_0$, the reactor unsaturates and observation of the flux-current curve illustrates that this must occur when $i=0$. Thus,

$$i(t_0)=0 \tag{3}$$

The final boundary condition required is the voltage across the capacitor at $t=t_0$. At the instant the switch opens, charge on the capacitor is zero, and therefore

$$v_c(t_0)=0 \tag{4}$$

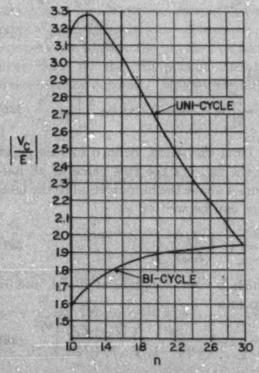

Fig. 6. Capacitor voltage step-up versus nonresonant frequency ratio

The original physical circuit has been formulated as a mathematical problem and its solutions can now be obtained. In the analysis that follows, it is assumed that $n \neq 1$ (the resonant case is not valid in the derivation) and since circuit frequencies greater than line frequency are being considered, $n>1$.

During saturation of the reactor (switch closed in Fig. 5) the circuit equation is

$$L\frac{di_1}{dt}=E\cos(wt+\phi) \tag{5}$$

Separating variables, integrating, and using equation 1,

$$i_1=\frac{E}{wL}[\sin(wt+\phi)-\sin\phi] \tag{6}$$

for $0 \leq t \leq t_0$

An equation relating t_0 and ϕ can be obtained by utilizing equation 3 resulting in

$$\sin(wt_0+\phi)=\sin\phi \tag{7}$$

To obtain the solution valid in the interval $(0, \pi/w)$, the supplement of ϕ must be employed in equation 7. Equating the appropriate arguments,

$$wt_0=\pi-2\phi \tag{8}$$

For the period of capacitor charge, the integrodifferential equation is

$$L\frac{di_2}{dt}+\frac{\int i_2 dt}{C}=E\cos(wt+\phi) \tag{9}$$

Rewriting this equation in terms of charge and using $w_0^2LC=1$,

$$\frac{d^2q}{dt^2}+w_0^2q=\frac{E}{L}\cos(wt+\phi) \tag{10}$$

This is a linear second-order ordinary differential equation whose solution can be readily obtained by any of several elementary methods. If Laplace transforms are employed, care must be exercised in defining the functions so that initial conditions at $t=t_0$ can be used.

Using equations 3 and 4, the solution of equation 9 is determined as

$$q(t)=\frac{n^2CE}{(n^2-1)}\Big[\cos\phi\cos n(wt+2\phi-\pi)+ \frac{1}{n}\sin\phi\sin n(wt+2\phi-\pi)+ \cos(wt+\phi)\Big] \tag{11}$$

Differentiating both sides of equation 11,

$$i_2(t)=\frac{n^2wCE}{(n^2-1)}[\sin\phi\cos n(wt+2\phi-\pi)- n\cos\phi\sin n(wt+2\phi-\pi)- \sin(wt+\phi)] \tag{12}$$

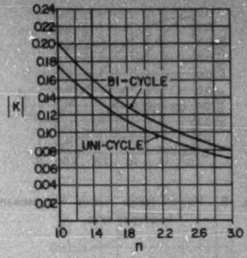

Fig. 7. Reactor turns-area design factor versus nonresonant frequency ratio

Utilizing equation 2, the following trigonometric relation is obtained:

$$\sin\phi\cos 2\phi n-n\cos\phi\sin 2\phi n- \sin(\pi+\phi)=0 \tag{13}$$

The expression in equation 13 can be factored leading to

$$\phi=\pi/2n \tag{14}$$

Substituting the value of ϕ from equation 14 into equations 11 and 12, the solutions for capacitor voltage and line current are obtained during the period of capacitor charge.

$$v_c(t)^{\dagger}=\frac{n^2E}{(n^2-1)}\Big[\cos\left(wt+\frac{\pi}{2n}\right)- \cos\frac{\pi}{2n}\cos n(wt-\pi)- \frac{1}{n}\sin\frac{\pi}{2n}\sin n(wt-\pi)\Big] \tag{15}$$

$$i_2(t)=\frac{n^2wCE}{(n^2-1)}\Big[n\cos\frac{\pi}{2n}\sin n(wt-\pi)- \sin\frac{\pi}{2n}\cos n(wt-\pi)- \sin\left(wt+\frac{\pi}{2n}\right)\Big] \tag{16}$$

$wt_0 \leq wt \leq \pi$

Inserting the value of ϕ obtained from equation 14 into equation 6, the solution for line current during reactor saturation is

$$i_1(t)=n^2wCE\left[\sin\left(wt+\frac{\pi}{2n}\right)-\sin\frac{\pi}{2n}\right] \tag{17}$$

Use was made of the relation $1/wL=n^2wC$ in deriving equation 17. Using equation 14, t_0, the point at which the reactor unsaturates, can be expressed as a function of n, namely,

$$wt_0=\frac{(n-1)\pi}{n} \tag{18}$$

Peak capacitor voltage, V_c, can be obtained easily from equation 15; for since

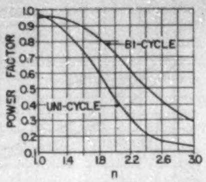

Fig. 8. Power factor versus nonresonant frequency ratio

$$V_c = v_c\left(\frac{\pi}{w}\right)$$

it follows that

$$V_c = \frac{-2n^2E}{n^2-1}\cos\frac{\pi}{2n} \tag{19}$$

with the negative sign the result of choosing polarities as in Fig. 4(A). A curve of $|V_c/E|$ as a function of nonresonance ratio is illustrated in Fig. 6.

One of the most important considerations for the design and evaluation of the first-stage reactor is the turns-area product required for saturation to occur at the proper point of the voltage waveform across the reactor.

From Faraday's law, one can derive

$$NA = \frac{-(10)^8}{\Delta B}\int v_c(t)\,dt \tag{20}$$

For the waveforms under examination, this integral is

$$\int_0^{\frac{\pi}{w}} v_c(t)\,dt$$

which in view of equation 15 becomes

$$\int_{t_0}^{\frac{\pi}{w}} v_c(t)\,dt = \frac{-2E}{w}\sin\frac{\pi}{2n} \tag{21}$$

Substituting this value in equation 20,

$$NA = \frac{2(10)^8E}{w\Delta B}\sin\frac{\pi}{2n} \tag{22}$$

In any practical pulser, circuit losses will reduce the theoretical charging circuit step-up ratio (V_c/E) indicated by equation 19 so that writing equation 22 in terms of V_c would be more useful. Making the appropriate substitution from equation 19, equation 22 becomes

$$NA = \frac{-(n^2-1)\,V_c(10)^8\tan\dfrac{\pi}{2n}}{n^2w\Delta B}$$

Using the familiar form for this quantity,

$$NA = K\,\frac{V_c(10)^8}{\Delta Bf} \tag{23}$$

where

$$K = -\frac{(n^2-1)}{2\pi n^2}\tan\frac{\pi}{2n} \tag{24}$$

A plot of $|K|$ as a function of nonresonance ratio is shown in Fig. 7.

Another important consideration in these high-powered pulsers is line power factor. Due to the large power drain from the source, poor power factor would be detrimental in applications where generator size is critical, e.g., in aircraft and missiles. In order to calculate power factor, rms current is needed and defined in the usual manner,

$$I_{\text{rms}} = \left[\frac{w}{\pi}\left(\int_0^{t_0} i_1^2dt + \int_{t_0}^{\pi/w} i_2^2dt\right)\right]^{1/2} \tag{25}$$

Evaluating the integrals in equation 25 using equations 16, 17, and 18,

$$I_{\text{rms}} = nwCE[F_1+F_2]^{1/2} \tag{26}$$

where

$$F_1 = \frac{n}{2}\left[(n-1)\left(2-\cos\frac{\pi}{\pi}\right) - \frac{3n}{\pi}\sin\frac{\pi}{n}\right] \tag{27}$$

and

$$F_2 = \frac{n}{4(n^2-1)^2}\left[(n^2+3)+(n^2-1)\cos\frac{\pi}{n} - \frac{2n(n^2+3)}{\pi(n^2-1)}\sin\frac{\pi}{n}\right] \tag{28}$$

Since the lossless circuit is being considered, power input equals the power discharged by capacitor C_1 which is

$$\frac{1}{2}CV_c^2r \tag{29}$$

In the bi-cycle case, $r=2f$ and therefore, $P=CV_c^2f$. Substituting for V_c,

$$P = \frac{2wCn^4E^2}{\pi(n^2-1)^2}\cos^2\frac{\pi}{2n} \tag{30}$$

Using equation 26, input volt-amperes is

$$nwCE^2\left[\frac{F_1+F_2}{2}\right]^{1/2} \tag{31}$$

From equations 30 and 31,

$$\text{Power factor} = \frac{2n^3\cos^2\dfrac{\pi}{2n}}{\pi(n^2-1)^2}\left[\frac{2}{F_1+F_2}\right]^{1/2} \tag{32}$$

where F_1 and F_2 are defined by equations 27 and 28. A graph of power factor (pf) versus n is shown in Fig. 8.

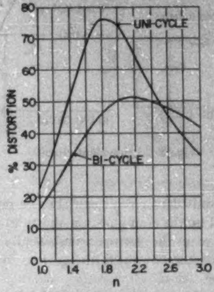

Fig. 9. Line-current distortion versus nonresonant frequency ratio

The final derivation to be made in the bi-cycle mode is the calculation of line-current distortion. Due to generator characteristics in certain systems, high harmonic content in the pulser input current could distort the voltage waveform of the source disturbing the operation of the other equipment. In order to calculate distortion, the rms amplitude of the fundamental is required and this can be easily obtained from the coefficients of the fundamental components of the Fourier series. Defining these quantities in the usual way and using the property for both i_1 and i_2 that

$$i(t) = -i\left(t-\frac{\pi}{w}\right)$$

$$I_f = \frac{w\sqrt{2}}{\pi}\left[\left(\int_0^{\pi/w} i(t)\cos wtdt\right)^2 + \left(\int_0^{\pi/w} i(t)\sin wtdt\right)^2\right]^{1/2} \tag{33}$$

Performing the required integrations, one obtains

$$I_f = \frac{n^2wCE}{\pi(n^2-1)}[2(F_3^2+F_4^2)]^{1/2} \tag{34}$$

where

$$F_3 = \frac{1}{2}\left[\pi(n^2-n-1) - n^2\sin\frac{\pi}{n}\right]\sin\frac{\pi}{n} + \frac{2n^2}{n^2-1}\cos\frac{\pi}{2n} \tag{35}$$

and

$$F_4 = \frac{1}{2}\left[\pi(n^2-n-1) - n^2\sin\frac{\pi}{n}\right]\cos\frac{\pi}{n} \tag{36}$$

Total distortion, defined in this paper as the ratio of the rms value of all harmonics above the fundamental to the total rms, can be written as

$$D = \left[1-\left(\frac{I_f}{I_{\text{rms}}}\right)^2\right]^{1/2} \tag{37}$$

which in view of equations 26, 34, and 37 becomes

$$D = \left[1-\left(\frac{2n^2}{\pi^2(n^2-1)^2}\right)\frac{(F_3^2+F_4^2)}{(F_1+F_2)}\right]^{1/2} \tag{38}$$

A plot of D versus n is illustrated in Fig. 9.

Analysis of Uni-Cycle Mode

The analysis of the uni-cycle mode differs from bi-cycle chiefly in the effect of bias current on the equivalent circuit and boundary values. The ideal flux-current characteristic of Fig. 3(A) is still applicable; however, current must now be interpreted as the total reactor current. Assuming a 1-to-1 turns ratio between main and bias windings, the flux-current characteristic for the current in the main winding is as illustrated in Fig. 3(B) with I_b representing the d-c bias current. Thus, the major change from bi-cycle operation is the current drawn by the reactor during unsaturation. In the equivalent circuit, this additional branch current must be taken into account as shown in Fig. 5(B). Polarities for the analysis are selected as in the waveforms of Fig. 4(B).

Boundary values are deduced as in the bi-cycle case and require revision only with respect to the additional branch current, I_b. At $t=0$, $dv_c/dt=0$ so that

$$i_c(0)=0 \tag{39}$$

Since $i=i_c+I_b$,

$$i(0)=I_b \tag{40}$$

The other conditions are

$$i(t_0)=I_b \tag{41}$$

$$i\left(\frac{2\pi}{w}\right)=I_b \tag{42}$$

and

$$v_c(t_0)=0 \tag{43}$$

In the bi-cycle case, waveforms are symmetrical over the entire cycle which results in a zero d-c component. In the uni-cycle mode, however, current waveforms are not symmetrical. Therefore, it is imperative to state the physical requirement that no d-c component can be present in line current. Mathematically,

$$\int_0^{\frac{2\pi}{w}} i(t)dt=0 \tag{44}$$

The circuit equation during saturation is

$$L\frac{di_1}{dt}=-E\cos(wt+\phi) \tag{45}$$

and the solution using equation 40 is

$$i_1=-\frac{E}{wL}[\sin(wt+\phi)-\sin\phi]+I_b \tag{46}$$

for $0\leq t\leq t_0$

Using equation 41, one obtains

$$wt_0=\pi-2\phi \tag{47}$$

as the solution for t_0 in the interval $(0, 2\pi/w)$.

During capacitor charge, the equation becomes

$$L\frac{d}{dt}(ic+I_b)+\frac{\int i_c dt}{C}=-E\cos(wt+\phi) \tag{48}$$

Since I_b is constant, this reduces to

$$L\frac{di_c}{dt}+\frac{\int i_c dt}{C}=-E\cos(wt+\phi) \tag{49}$$

This equation, other than for polarity of driving voltage, is identical to the bi-cycle mode equation, and the solution can be written directly. Since $i_2(t)=i_c+I_b$, the solution for line current is

$$i_2(t)=I_b+\frac{n^2wCE}{(n^2-1)}[n\cos\phi\sin n\times(wt+2\phi-\pi)-\sin\phi\cos n\times(wt+2\phi-\pi)+\sin(wt+\phi)] \tag{50}$$

and capacitor voltage is

$$v_c(t)=-\frac{n^2E}{(n^2-1)}\left[\cos\phi\cos n\times(wt+2\phi-\pi)+\frac{1}{n}\sin\phi\sin n\times(wt+2\phi-\pi)+\cos(wt+\phi)\right] \tag{51}$$

Using equation 42 in equation 50, one obtains

$$n\cos\phi\sin n(\pi+2\phi)-\sin\phi\times\cos n(\pi+2\phi)+\sin\phi=0 \tag{52}$$

This can be factored leading to the solution.

$$\phi=\frac{\pi}{n}-\frac{\pi}{2} \tag{53}$$

Substituting this value of ϕ in equations 50 and 51,

$$i_2(t)=I_b+\frac{n^2wCE}{(n^2-1)}\left[n\sin\frac{\pi}{n}\sin n(wt-2\pi)+\cos\frac{\pi}{n}\cos n(wt-2\pi)-\cos\left(wt+\frac{\pi}{n}\right)\right] \tag{54}$$

and

$$v_c(t)=-\frac{n^2E}{(n^2-1)}\left[\sin\frac{\pi}{n}\cos n(wt-2\pi)-\frac{1}{n}\cos\frac{\pi}{n}\sin n(wt-2\pi)+\sin\left(wt+\frac{\pi}{n}\right)\right] \tag{55}$$

Substituting this value of ϕ from equation 53 into equation 46, and using $1/wL=n^2wC$,

$$i_1(t)=n^2wCE\left[\cos\left(wt+\frac{\pi}{n}\right)-\cos\frac{\pi}{n}\right]+I_b \tag{56}$$

and the point of unsaturation becomes

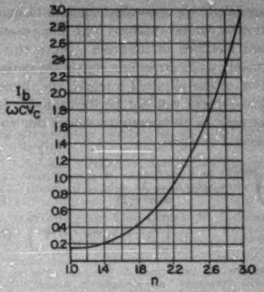

Fig. 10. Normalized bias current versus nonresonant frequency ratio

$$wt_0=\frac{2\pi(n-1)}{n} \tag{57}$$

Using equation 55,

$$V_c=v_c\left(\frac{2\pi}{w}\right)=\frac{-2n^2E\sin\frac{\pi}{n}}{n^2-1} \tag{58}$$

and a plot of $|V_c/E|$ versus n is illustrated in Fig. 6.

To determine I_b, equation 44 will be utilized. Therefore,

$$0=\int_0^{\frac{2\pi}{w}} i(t)dt=\int_0^{t_0} i_1(t)dt+\int_{t_0}^{\frac{2\pi}{w}} i_2(t)dt \tag{59}$$

Evaluating the integrals and solving,

$$I_b=n^2wCE\left[\frac{n^2}{\pi(n^2-1)}\sin\frac{\pi}{n}+\frac{(n-1)}{n}\cos\frac{\pi}{n}\right] \tag{60}$$

As in the case for NA, bias current in terms of V_c rather than E would be more useful and informative. Making the appropriate substitution,

$$I_b=-\frac{wCV_c}{2}\left[\frac{n^2}{\pi}+\frac{(n^2-1)(n-1)}{n}\cot\frac{\pi}{n}\right] \tag{61}$$

A curve of normalized bias current, I_b/wCV_c versus n (disregarding polarity) is illustrated in Fig. 10.

Computation of the volt-second integral for evaluating NA is more complicated for uni-cycle than bi-cycle due to the reversal of polarity of $v_c(t)$. A necessary preliminary, therefore, is the determination of the zero crossover, t_1. Since $v_c(t_1)=0$,

$$\sin\frac{\pi}{n}\cos n(wt_1-2\pi)-\frac{1}{n}\cos\frac{\pi}{n}\sin n\times(wt_1-2\pi)+\sin\left(wt_1+\frac{\pi}{n}\right)=0 \tag{62}$$

Unfortunately, equation 62 cannot be solved explicitly for t_1. However, for any specified n, a numerical solution of equation 62 can be obtained for t_1 using standard methods of iteration. Since this is merely an intermediate step in the derivation of the required integral, the numerical process will not be illustrated. Returning to the computation of the volt-second integral,

$$\int_{t_1}^{2\pi/w} v_c(t)\,dt = \frac{E}{w(n^2-1)} \times \left[(n^2-1)\cos\frac{\pi}{n} + F_5\right] \qquad (63)$$

where

$$F_5 = n \sin\frac{\pi}{n}\sin n(wt_1 - 2\pi) + \cos\frac{\pi}{n}\cos n(wt_1-2\pi) - n^2\cos\left(wt_1 + \frac{\pi}{n}\right) \qquad (64)$$

Utilizing equation 62, F_5 can be evaluated numerically as a function of n.

Inserting V_1 from equation 58 into equation 63,

$$\int_{t_1}^{2\pi/w} v_c(t)\,dt = -\frac{V_c}{2n^2 w \sin\frac{\pi}{n}} \times \left[(n^2-1)\cos\frac{\pi}{n} + F_5\right] \qquad (65)$$

Using the same form for NA as in equation 23,

$$K = -\frac{(n^2-1)\cos\frac{\pi}{n} + F_5}{4\pi n^2 \sin\frac{\pi}{n}} \qquad (66)$$

A plot of $|K|$ for the uni-cycle mode of operation is illustrated in Fig. 7. Calculating I_{rms} for computation of power factor,

$$I_{rms} = n^2 wCE[F_6 + F_7]^{1/2} \qquad (67)$$

where

$$F_6 = \frac{(n-1)}{n}\left[\frac{1}{2} + \left(I_{bn} - \cos\frac{\pi}{n}\right)^2\right] + \frac{1}{2\pi}\left[3\cos\frac{\pi}{n} - 4I_{bn}\right]\sin\frac{\pi}{n} \qquad (68)$$

$$F_7 = \frac{I_{bn}^2}{n} + \frac{n^2+3}{4n(n^2-1)^2} - \frac{1}{4n(n^2-1)} \times \cos\frac{2\pi}{n} - \frac{2I_{bn}}{\pi(n^2-1)}\sin\frac{\pi}{n} + \frac{(n^2+3)}{4\pi(n^2-1)^3}\sin\frac{2\pi}{n} \qquad (69)$$

and

$$I_{bn} = \frac{I_b}{n^2 wCE} \qquad (70)$$

From equation 67,

Input volt-amperes

$$= n^2 wCE^2\left[\frac{F_6+F_7}{2}\right]^{1/2} \qquad (71)$$

Since in uni-cycle there is only one pulse per cycle,

$$P = \frac{1}{2} CV_c^2 f \qquad (72)$$

Using equation 58,

$$P = \frac{n^4 wCE^2}{\pi(n^2-1)^2}\sin^2\frac{\pi}{n} \qquad (73)$$

Utilizing equations 71 and 73,

$$\text{Power factor} = \frac{n^2}{\pi(n^2-1)^2} \times \left[\frac{2}{F_6+F_7}\right]^{1/2}\sin^2\frac{\pi}{n} \qquad (74)$$

The curve of pf is illustrated in Fig. 8.

To calculate distortion, the fundamental rms amplitude of line current is required. Deriving this quantity, one obtains

$$I_f = n^2 wCE\left[\frac{F_8^2+F_9^2}{2}\right]^{1/2} \qquad (75)$$

where

$$F_8 = \frac{1}{(n^2-1)}\left[(n^2-n-1)\cos\frac{\pi}{n} + \frac{n^2}{2\pi}\cos\frac{\pi}{n}\sin\frac{2\pi}{n} - \frac{2n^2}{\pi(n^2-1)} \times \sin\frac{\pi}{n}\right] \qquad (76)$$

and

$$F_9 = \frac{1}{(n^2-1)}\left[(n^2-n-1)\sin\frac{\pi}{n} + \frac{n^2}{2\pi}\sin\frac{\pi}{n}\sin\frac{2\pi}{n}\right] \qquad (77)$$

Calculating total distortion as in bi-cycle and using equations 67 and 75,

$$D = \left[1 - \frac{F_8^2+F_9^2}{2(F_6+F_7)}\right]^{1/2} \qquad (78)$$

D versus n is shown in Fig. 9.

Discussion

Examination of Figs. 6–10 reveals many interesting aspects of nonresonant charging. It is apparent from Fig. 7, that a faster charging rate for the input stage results in a considerable reduction of first-stage reactor NA and consequently of core volume. This characteristic applies for both modes of operation.

Fig. 6 indicates that capacitor voltage step-up increases with charging circuit frequency in the bi-cycle case up to a maximum step-up of 2.0. For the uni-cycle mode, however, after the maximum is reached at a ratio of 1.2, voltage step-up is reduced with increasing frequency. In evaluating performance, this characteristic is actually unimportant since, in most pulsers, an input transformer is required to raise the voltage to the desired level and the transformer turns ratio can be altered to take the actual step-up voltage into account. In practical pulsers the values in Fig. 6 will have to be revised to take into account actual circuit losses, such as those due to the charging choke and the core loss in the first stage reactor.

The pf curves of Fig. 8 illustrate another difference between the two modes of operation. In bi-cycle, pf actually rises as n is increased from resonance and remains above 90% until $n=1.55$ is exceeded. For frequency ratios to 1.8, pf's greater than 80% can be obtained. In uni-cycle, however, pf drops off sharply as n is increased above resonance. To obtain a pf of 90%, n must be limited to less than 1.3, and for a pf of 80%, n cannot exceed 1.5. On the basis of pf alone, the n which could be utilized in the uni-cycle mode is limited to a fairly low value.

The nature of line-current distortion, as illustrated in Fig. 9, is quite evident. In applications where the harmonic content of the current drawn from the generator is critical, nonresonance could not be employed. In many applications, however, distortion has not been critical and interference with other equipment using the same generator has been negligible. As one would expect, the nonsymmetrical waveforms of uni-cycle operation result in higher distortion than for bi-cycle. In actual pulsers, the cores do not saturate so sharply as shown in the ideal magnetization curves utilized in the derivation; consequently, distortion is usually less than that predicted from the analysis.

The bias current curve of Fig. 10 offers another reason why higher values of n are impractical in the uni-cycle mode. Bias current rises gradually with nonresonance, and for $n=1.5$ an increase of approximately 50% is obtained. For greater value of n, bias increases sharply and becomes excessive.

The principal advantage of nonresonant charging circuits is the reduction in core volume accomplished by faster charging rates. For bi-cycle operation, $n=1.5$ results in a reduction of 25% of NA and in a pf greater than 90%. In the unicycle case, the reduction in NA is approximately the same, but due to lower pf, higher distortion, and increased bias, n must be limited to values less than 1.3. In practice, the choice of charging circuit frequency depends on a compromise between reduced core volume and increased demand on the power supply.

Performance at resonance can be obtained either by using the basic equations of the resonant circuit or by taking the limit as n approaches unity in the equations of this paper. Although the derivation is not valid for $n=1$, the solution for resonance exists as a limiting value. In the case of the more involved equations, it is simpler to use the resonant circuit equations. The limiting process, however, is nevertheless advisable to provide a check on the validity of the analysis. The ideal magnetization curve is a close approximation for equipment of this type and good agreement has been obtained with experimental data. It should be understood that the curves presented here are not intended as accurate design criteria but merely indicate general performance and trends. The results of an ideal analysis are sufficiently close so that equipment based on it should require only minor modifications.

Conclusions

A nonresonant charging circuit for magnetic pulse generators has been analyzed by employing piecewise linear methods. The most pertinent design considerations have been summarized graphically for both the uni-cycle and bicycle modes of operation. It has been shown that the advantages gained in core volume reduction must be weighed against increased demands on the power supply.

The Definition and Measurement of the Time Constant and Response Time of Thermal Converters

FRANCIS L. HERMACH
MEMBER AIEE

Synopsis: The dynamic characteristics of a thermal converter for measuring alternating current or voltage are of some importance in a number of applications. The time constant and response time are the characteristics most often required. The change of emf (electromotive force) of a thermal converter after a step change in heater current is only approximately exponential, so that the definition as well as methods of measuring these quantities must be specified. This investigation of methods of measuring these quantities was undertaken at the request of the AIEE Committee on Indicating and Integrating Instruments.

A THERMAL CONVERTER (often called a thermoelement or thermocouple) consists of a thermojunction in thermal contact with an electric heater, so that the output emf serves as a measure of the heater current.[1] Thermal converters are finding increasing use as primary elements for measuring alternating current and voltage, because of their d-c output and wide frequency range, and as a-c–d-c transfer standards, because the transfer may be made very accurately with properly constructed converters. They are also valuable as detectors for noise studies (with suitable amplifiers), because they integrate to give the rms (root-mean-square) value of a signal. In each application the dynamic characteristics are of some importance. These characteristics are usually evaluated in terms of either a time constant of the change of emf after a step change in heater current, or a response time for essentially all of the change to take place.

The time constant t_c of a simple exponential function of an independent variable t is the value of t required for $100(\epsilon-1)/\epsilon$ per cent (63.2%) of the total change in the dependent variable, where ϵ is the base of the natural logarithms. However, for most converters the change of emf is only approximately exponential. Thus a definition must precede the selection of a method for making the measurements. One definition, which we shall call t_a, is the time in seconds required for 63% of the change to take place. Another which has been proposed is given by the expression $t_b=(1/E)\int_0^\infty e\,dt$, where e is the difference between the final emf and the actual emf at the time t, and E is the difference between the final and initial emf's, as shown in Fig. 1. Both of these reduce to t_c for a simple exponential function.

A dynamic characteristic of interest in ordinary instrument applications is the response time. This is defined for an indicating instrument[1] as the time required for the pointer of the instrument to come to apparent rest after an abrupt change has occurred in the measured quantity. The pointer is considered to have come to apparent rest when it remains within a range on either side of its final position equal to 1/2 the accuracy rating of the instrument.

When a thermal converter is used as a primary element in an instrument, its response time may be more important than its time constant. The usual thermocouple instruments are in about 1% accuracy class and the scale of a thermocouple instrument is nearly square law, so that $dD/D=2dI/I$, where D is the instrument deflection and I is the heater current. Since the deflection is proportional to the emf of the converter it follows that the time required for 90% of the change in emf to take place could appropriately but somewhat arbitrarily be considered as the response time. However, at least one manufacturer has for a

number of years used the 90%-response time in specifying the dynamic characteristics of his thermal converters, perhaps because this is easier to measure. There is thus a need for precise definitions and experimental studies of actual converters.

Measurements

Several methods of measuring the dynamic characteristics of thermal converters were considered, from the viewpoints of practicality, accuracy, and the commercial availability of apparatus. The time constants and response times of a group of several types of thermal converters were measured by two of the most promising methods, with every reasonable effort to obtain an accuracy of 2% in the measurement. These converters had time constants ranging from 0.1 to 10 seconds.

GALVANOMETER METHOD

The first of these two methods consisted simply of obtaining and scaling oscillograms of the output emf of each converter as a function of elapsed time after a prescribed step change in heater current. Step changes from zero to the prescribed current and vice versa were used (current switched on and off, respectively). The records were made with a direct-writing electromagnetic oscillograph consisting of a "penmotor" galvanometer with a chart drive of 5, 25, and 125 mm (millimeters) per second and a d-c amplifier which provided about 0.7 of critical damping for the galvanometer. The over-all gain of the amplifier was such that a chart deflection of 40 divisions (40 mm) could easily be obtained at 5 millivolts, with a noise level of about 10 microvolts.

To eliminate errors caused by nonuniformity of the response of the amplifier or the galvanometer and by drifts in the gain of the amplifier, oscillograms were taken, immediately after each measurement, of calibrated direct voltages equal to 37% and 63% of the emf of the converter. To verify the accuracy of the chart drive, oscillograms were periodically taken of amplified seconds pulses from the National Bureau of Standards radio station *WWV*. To reduce timing errors, a second timing pen was energized when the step change in heater current was applied, and the coincidence of the two pens was occasionally carefully checked.

The circuit for making these measurements, with heater current switched either on or off, is shown in Fig. 2. Twisted pair wires were used to minimize inductive loops in both the heater and thermocouple circuits. With switches S_1 and S_4 closed, S_3 open, and S_2, which controlled the timing pen, closed to the left, the heater current I_h was adjusted to the desired value, and the Lindeck-potentiometer current I_p was adjusted for a null balance of the indicating galvanometer G. Switches S_4 and S_5 were then opened, S_3 was closed, the chart drive was energized, and S_1 was first opened and then closed to obtain oscillograms of decreasing and increasing emf. S_5 was then reversed and, with S_1 open, I_p was successively set at 37% and 63% of the value at balance, to calibrate the oscillograph. The time constant t_a and the 90% response time were measured from these calibrated oscillograms.

The 99% response times of a few converters were measured by increasing the gain of the amplifier and offsetting the zero so that a galvanometer deflection of about 30 divisions was obtained for about 10% of the full emf of the converter. The measurements were then repeated along with a calibrating trace differing by about 3% from the full emf.

It is estimated that the galvanometer deflection corresponding to 63% of the change in emf could be determined at best to 0.2 mm on the 40-mm voltage and the chosen time scale. The resultant uncertainties in the measurement of the time constant in seconds are believed to be less than $\pm(2\%+0.4/p)$, where p is the chart speed: 5, 25, or 125 mm/second. Other sources of error are believed to be much less than this for most of the converters tested.

The speed response of the galvanometer system determines, of course, the lower limit of the time constant which may be measured with a given error by the oscillograph. This limit was calculated for an exponential forcing function of time constant t_e applied to a critically damped galvanometer of period t_0. As shown in Appendix I the error should be less than 3% if $t_0/t_e<0.1$, which was true for all but one of the converters tested. While this galvanometer was underdamped and some nonlinearity was introduced in the amplifier by the manufacturer to increase its frequency range for sinusoidal signals, it is believed that this indicates closely enough the error that may be expected from this cause.

FLUXMETER METHOD

A fluxmeter based on the "Inductronic Amplifier"[2] has been used by engineers of the Weston Electrical Instrument Corporation to measure time constants of thermal converters. Although this instrument was not immediately at hand, a commercial, multirange pointer-type fluxmeter was available, and proved to be entirely suitable for measurements of t_b. Such a fluxmeter consists of a permanent-magnet-moving-coil instrument having ligaments of very little restoring torque, rather than spiral springs, to carry the current to the moving coil. Under appropriate conditions the change of deflection of the instrument in a circuit of fixed resistance is $D=K\int e\,dt$ where e is the net emf in the circuit. Thus if the instrument is connected to the output of a thermal converter in such a way that e is the desired change in emf, we have $t_b=(1/E)\int e\,dt=D/EK$. For a converter with a 10-second time constant, the fluxmeter must integrate correctly over a period of about 50 seconds. The conditions which must be met to assure this are considered in Appendix II.

The 5-range, portable fluxmeter available had sensitivities from 0.1 to 10 millivolt-seconds per division in a 15-ohm circuit, with a 100-division mirrored scale. It was used to measure the time constants of the same group of converters, with the circuit shown in Fig. 3. To make a

measurement, switch S was closed, the heater current I_h was adjusted to the desired value, I_p was adjusted for a balance as indicated by absence of motion of the pointer of the fluxmeter (on the most sensitive range), and R_2 was set so that the resistance of the circuit as seen by the fluxmeter (including the thermocouple) was 15±0.2 ohms, the design value. The switch was then successively opened and closed and the changes in deflection of the fluxmeter pointer were observed. The constant K was determined at the beginning and end of the entire series of tests by measuring with an electric timer the time required for a given deflection of the pointer, with a constant measured current I_p, with R_2 set as above, and with $I_h=0$. To make sure that the switch blades operated simultaneously, a 4-terminal resistor was substituted for the thermal coverter and the switch was opened and closed several times with I_p set for a balance on the most sensitive range of the instrument. The changes in deflections did not exceed 0.1 division on the scale.

OTHER METHODS

A method of measuring t_b has been developed in which the rise of emf of a converter is opposed to the rise of voltage in an RC circuit, with a ballistic galvanometer as the detector. (Private communication from R. Gilbert to the author.) The circuit diagram is shown in Fig. 4. The resistor R_1 is adjusted to secure a steady state null, and C is then adjusted to produce a transient null when the switch is operated. The null point is defined as the condition of zero integral of voltage at the balance detector. When $R_2 >> R_1$ the R_1C product (in ohms and farads) is the time constant t_b of the converter. The method is not readily adaptable to the full range of time constants of 0.1 to 10 seconds encountered in converters, and it requires a very sensitive ballistic galvanometer, so that the fluxmeter method was used in these tests instead.

The time constant t_a and response time can be measured with a suitable relay which is connected directly to the output of the converter and adjusted to close at the desired millivolt level, to control an electric interval timer. This method, which seems promising, was not tried, because suitable high-speed relays and d-c amplifiers were not readily available.

For some applications the response of a converter to a low-frequency sinusoidal alternating current is of interest. At very low frequencies large-amplitude periodic oscillations of emf occur; the amplitude of these oscillations can be used to estimate the time constant. Calculations show that for converters which are perfectly "square-law," frequencies of about $0.2/t_e$ cycles per second are required to produce an oscillation having a crest value which is 37% of the average value of the output emf. However, the resulting frequency range of 0.02 to 2 c/s is a difficult one in which to work. In addition, nonlinearities in practical converters would probably greatly impair the accuracy of computing t_e from frequency response curves, or vice versa.

Results

The results of measurements of the time constants of representative thermal converters by both methods are given in Table I. The results of measurements of the 99% response time t_r by the oscillographic method are also given. The converters are identified in the table by type and are further described as follows: all converters below 1,000 ma (milliamperes), except no. 7 and no. 8, are of the vacuum type, mounted in an evacuated glass bulb. The 1- and 5-ampere converters have short solid-wire or tubular heaters connected between comparatively large copper blocks. Each bead-type converter has a small electrically insulating bead between the heater and the hot junction of the thermocouple. In the contact type the heater and thermocouple are electrically connected. In the bridge type they are in the same bridge circuit (measurements were made with 60 cycles per second alternating current through the heater). Converter no. 2 is an ultrahigh-frequency type having the heater in line with the lead-in wires. Converter no. 3 is a converter with a heater 1 centimeter long (about twice normal) to obtain good low-frequency performance. Converter no. 4 has an unusually large insulating bead to obtain a long time constant.

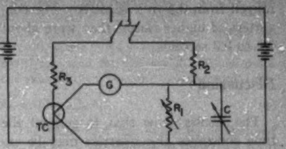

Fig. 4. Circuit for "bridge" method

G—Galvanometer
TC—Thermal converter

The measured time constants of the converters ranged from 0.1 second for a bridge-type converter to over 8 seconds for the special converter having the large insulating bead between the heater and thermocouple. For the usual converters in the milliampere ranges, time constants

ranged from 0.5 to 2 seconds. For converters of higher range, they were about 0.2 to 0.3 seconds.

Discussion

The results show that in general the time constants of converters may be expected to be dependent upon both the magnitude and direction of the step of heater current, with changes of 20% in some cases. Thus any specification of the time constant must include the conditions of test if accuracies better than this are desired

The measured time constants t_a and t_b generally differed from each other under the same test conditions by only a few per cent. Large differences, up to 50%, were obtained in a few cases, however. As a check these differences were verified for converters no. 6, no. 9 and no. 10 by carefully measuring the areas and ordinates on the oscillograms used for measuring t_a, and then calculating t_b. The calculated values agreed with the fluxmeter values of t_b to 3 per cent or better.

There are several causes of the depedence of both t_a and t_b upon the heater current, and also of the differences between t_a and t_b for the same current. They may be listed as follows:

1. Thomson effect in the thermocouple wires, which causes the emf versus temperature characteristic of the thermocouple to be nonlinear.
2. Nonlinearities caused by temperature dependence of the heating and cooling coefficients of the heater.
3. Temperature rise of the junctions between the lead-in-wires and the heater or thermocouple wires.
4. The fact that the heater is a complex thermal body with no single time constant.

These were investigated theoretically to determine the approximate magnitudes of their effects.

As shown in Appendix III, a nonlinear relation between the temperature rise and the output emf of the thermocouple of a converter can cause both t_a and t_b to be dependent on the magnitude and direction of the change in heater current. For the materials normally used in thermal converters, this effect would not be expected to cause t_a or t_b to differ by as much as 1%, and would cause either one to change by no more than 3 or 4%, as the step change in heater current is increased to rated value. In addition it would cause the change in time constant with current switched on to be equal and opposite to that with current switched off. This does not fit the observed patterns of Table I, for, in general, the low-current values are larger than those at rated current, with current switched either on or off.

Nonlinearities in the heater circuit can be caused by temperature dependence of either the heating or cooling coefficients. For most thermal converters heat is lost from the heater wire chiefly by conduction to the terminal blocks or lead-in wires. The change in temperature is thus a function of both time and the distance from the ends of the heater. Solutions for the resulting steady-state temperature distribution with nonlinear characteristics and with either direct or alternating current through the heater have been obtained.[3] Corresponding transient solutions should also be possible, but have not been attempted because of the complexity of the problem. Appendix IV gives an approximate solution for t_a and t_b for conductors with nonlinear lateral cooling only (convection and radiation). For these cases differences in t_a and t_b of almost 10% may be expected. Decreases in either t_a or t_b should be expected as the heater current is increased, with larger decreases (up to 70%) with the current switched on than with the current switched off. It is believed that similar patterns would be obtained for conduction cooling. Thus the nonlinearities in the thermocouple and heater account reasonably well in a semi-quantitative way for the observed typical dependence of the time constant of a converter upon the direction and magnitude of the change of heater current.

Neither of these effects can be expected to cause differences between t_a and t_b as large as those observed for converters no. 9 and no. 10 (20 to 50%). These differences are believed to be due to the temperature rise of the junctions between the heater and lead-in wires. Approximate calculations show that for these converters and for other glass-bulb converters of high-range (200–1,000 ma), the rise can be 5 to 10% of the temperature rise of the midpoint of the heater, with a time constant up to several times that of the heater wire alone. Formulas for t_a and t_b have been developed for the resulting case in which the change in emf is the sum of two unequal exponential terms, with results which seem in reasonable agreement with the observed differences.

Goodwin has shown[4] that the temperature rise of a conductor cooled by conduction to terminals at each end can be represented by a series of exponentials. The conductor is thus not a "simple thermal body." The series converges rapidly, however, and calculations indicate that the effect should cause t_a and t_b to differ by less than 1% and be independent of the current level.

Measurements showed that for all converters except no. 9 and no. 10 the ratio of the 90% response time, to the time constant, t_a, differed from that for a simple exponential (2.3) by less than 10%. For these it was 2.6 and 3.1 respectively. As shown in Table I, the ratio of the 99% time t_r to the time constant t_a differed appreciably from that for a simple exponential (4.6), for a large percentage of the few converters tested. Although additional converters should have been checked, this indicates that it may be desirable to directly measure rather than calculate t_r for those instrument applications in which this is the significant dynamic characteristic.

Summary and Conclusions

The change in emf of a thermal converter after a step change in heater current is not strictly exponential. Because of this two different definitions of an arbitrary time constant have been proposed for converters. One is the time required for 63% of the change in emf to take place, and the other is the time integral of the difference between instantaneous and final emfs divided by the total change in emf. Reasonably simple methods of measuring each have been demonstrated and the limitations on accuracy have been theoretically and experimentally determined. The results indicate that the two definitions generally (but not always) give the same result. For most of the 13 converters tested the differences were less than 5%, but for one the difference was almost 20% and for another 50%, under identical test conditions.

For most converters the measured time constants depend upon the magnitude and the direction (whether up or down) of the step change in heater current, with variations up to 10% rather common. Analysis indicates that these variations are very probably caused by nonlinearities in the heater and thermocouple. Discussions with manufacturers and users indicate that an accuracy of 10% is generally adequate in specifying time constants, although an accuracy of 5% is sometimes required. Because of the influences already noted, the time constant should be defined and the conditions of test should be specified. The author suggests a step change from zero to rated current as a standard condition in evaluating time constants of converters.

For many instrument applications the response time is of more importance than the time constant. For a thermal converter a definition of response time is suggested as the time required for 99% of the change in emf to take place after a step change from zero to rated current.

Because the same method and equipment may be used to measure the 63% and 99% response, the arbitrary 63% definition of "time constant" is believed by the author to be somewhat preferable to the definition based on the time integral of emf, if a choice must be made. (In a recent paper[5] the time for 63% change of response is also used as the criterion of the dynamic characteristics of thermocouples for temperature measurement, and is defined as the "characteristic time.") Calibration of the oscillograph would ordinarily not be necessary if an accuracy of 10% is sufficient, thus simplifying the test method considerably.

Inquiries indicate that the terms "time constant" and "response time" are often used loosely and even interchangeably, so that care must be taken in comparing or specifying values based upon them.

Appendix I. Error of Galvanometer Oscillograph with Exponential Forcing Function

The response of the idealized galvanometer (with a linear voltage amplifier of high input impedance) when the input voltage E decays exponentially with a time constant $t_c=1/k$, is given by the equation

$$P\frac{d^2\theta}{dt^2}+A\frac{d\theta}{dt}+U=E\epsilon^{-kt} \tag{1}$$

with the initial conditions $\theta_0=E/U$, and $d\theta/dt=0$ at $t=0$, where θ is the angular deflection, and P, A and U are the inertial, damping, and restoring constants respectively.[6]

For critically damped case, when $A^2=4PU$, the solution is

$$\theta=\frac{E}{Q}[\epsilon^{-kt}-(1-mt-kt)\epsilon^{mt}]+\frac{E}{U}(1-mt)\epsilon^{mt} \tag{2}$$

where $m=-A/2P=-2\pi/t_0=-\sqrt{U/P}$, $Q=Pk^2-Ak+U$, and t_0 is the free (undamped) period of the galvanometer. If the ratio n of the free period divided by the time constant is less than about 0.5, this becomes, closely enough, when $t=t_c$,

$$\theta_c=\frac{\theta_0}{\epsilon}\left(1+\frac{\eta}{\pi}\right) \tag{3}$$

Combining this with the approximate relation $\Delta\theta/\theta=-\Delta t/t_c$ shows that the error in measuring the time constant is about 30 t_0/t_c per cent. Since the period of the galvanometer used is about 0.02 second, an error of about $0.6/t_c$ per cent can be expected.

In general for $n<0.5$ and $t>t_c$ the response is $\theta=\theta_t\ (1+n/\pi)$ where θ_t is the response of galvanometer without error. Thus the error in measuring the 99% response time should be about $7t_0/t_c$ per cent, since $t_r=4.6\ t_c$.

It is tempting to consider measuring the response time of a converter by connecting it to a millivoltmeter and noting the time for 99% of the change in deflection to take place. While this gives a good measure of the minimum reading time of the combination, analysis shows that errors considerably larger than 10% would be expected for most converters ($t_c=0.2$ to 2 seconds), since the period of the usual sensitive millivoltmeter is about 2 seconds. This was borne out by a few informal tests of several converters with such a millivoltmeter.

Appendix II. Errors in Measuring t_b with a Fluxmeter

For an ideal fluxmeter having no restoring torque the equation of motion, neglecting inertial torque, is

$$A\frac{d\theta}{dt}=Gi \tag{4}$$

where i is the current through the moving coil and G is the motor constant. If an emf e is applied and the circuit is nonreactive, with a resistance R the resulting current is, $i=(e-e_b)/R$ where $e_b=Gd\theta/dt$. Thus

$$A'\frac{d\theta}{dt}=\frac{Ge}{R} \tag{5}$$

where

$$A'=A+G^2/R$$

When integrated from t_1 to t_2, this gives

$$A'(\theta_2-\theta_1)=\frac{G}{R}\int_{t_1}^{t_2}edt \tag{6}$$

without restriction on the duration of the time interval.

If $A\ll G^2/R$, the change in deflection is not dependent on R. In a shunted multirange fluxmeter, however, this is not usually the case.

There are several sources of error in using a fluxmeter in this way. If the errors are small, we may treat each source separately, since their combination will in general differ by second and higher order terms only.

The term $Pd^2\theta/dt^2$ must be added to equation 5 to account for the inertia of the moving system. However, if the moving system is stationary at the beginning and end of the time interval it is easy to show by direct integration that this causes no error. It can also be shown that no first-order error will be caused by the inductance of the circuit.

The limiting error for measurements at long time intervals is generally caused by the small restoring torque $U\theta$ of the suspensions (and in unbalanced instruments, by a gravitational couple). If the applied voltage e decays exponentially with a time constant $t_c=1/k$, we have

$$A'\frac{d\theta}{dt}+U\theta=\frac{GE\epsilon^{-kt}}{R} \tag{7}$$

with zero deflection defined as the rest position with no emf applied.

The solution of this equation, with $\theta=0$ at $t=0$, is $\theta=[S/(1-b)](\epsilon^{-bkt}-\epsilon^{-kt})$ where $b=U/kA'$ and $S=GE/kA'R$. When $b\ll1$ the maximum value of θ is approximately

$$\theta_m=S[1+b\ l_n\ b] \tag{8}$$

The value of b can easily be determined by observing the change in deflection from θ_0 to θ_1 in a measured time t_c, with $e=0$ and with the same circuit resistance. Then $A'd\theta/dt=-U\theta$, with $\theta=\theta_0$ at $t=0$, from which $b=\Delta\theta/\theta_0$ if $\Delta\theta=(\theta_0-\theta_1)\ll\theta_0$.

With an initial deflection of 60 divisions of the fluxmeter used in these tests, b was about 0.005 for $t_c=10$ seconds. Thus the restoring-torque error should be less than 3% for even the slowest converter tested.

Appendix III. Effect of Nonlinearity of the Thermocouple

When the heater current of a converter is switched off the temperature difference between the two junctions of the thermocouple may be represented by $\theta=\theta_0\epsilon^{-t/t_c}$. If the emf of the thermocouple is $e=\alpha\theta+\beta\theta^2$, with $\beta\ll\alpha$, direct substitution and integration gives

$$t_{b1}=\frac{1}{E}\int_0^\infty e\,dt=t_c\left(1-\frac{\beta\theta_0}{2\alpha}\right) \tag{9}$$

where E is the emf when $t=0$, and the subscript 1 refers to the condition, current switched off. When $e=E/\epsilon$ we find that, closely enough,

$$t_{a1}=t_c\left(1-\frac{0.6\beta\theta_0}{\alpha}\right) \tag{10}$$

When the current is switched on, we have $\theta=\theta_0(1-\epsilon^{-t/t_c})$ from which, in the same way

$$t_{b2}=t_c\left(1+\frac{\beta\theta_0}{2\alpha}\right) \tag{11}$$

and

$$t_{a2}=t_c\left(1+\frac{0.6\beta\theta_0}{\alpha}\right) \tag{12}$$

For the thermocouple materials ordinarily used in converters, $\beta/\alpha\approx+0.0004$ and $\theta_0\approx150$ C at rated heater current. Thus differences between t_a and t_b from this cause should not exceed 0.4% and both t_a or t_b should change by no more than 4% from low to rated current.

Appendix IV. Effect of Nonlinearities of the Heater

If we consider a conductor of uniform cross section, a, and circumference, c, heated by a steady current, I, suddenly applied, and with lateral cooling only, we have

$$asd\frac{d\theta}{dt}+h_0c\theta=\frac{I^2p}{a} \tag{13}$$

where d, s, and p are the density, specific heat, and resistivity of the conductor and h_0 is the cooling coefficient (watt/square centimeter degrees centigrade). If the initial conductor is $\theta=0$ at $t=0$ the solution is

$$\theta=\frac{g}{k_0}(1-\epsilon^{-k_0t}) \tag{14}$$

where $g=I^2p/a^2ds$, $k_0=h_0\ c/ads=1/t_c$, and t_c is the time constant of the temperature rise of the conductor.

The cooling coefficient h is in general temperature-dependent. For the moderate values of temperature rise in a converter we may approximate this by assuming that $h=h_0\ (1+\gamma\theta)$ where h_0 is the value at the reference temperature and γ is a constant. Temperature coefficients of the other quantities such as resistivity are in general less than γ for most converters. The differential equation then becomes

$$\frac{d\theta}{dt}+k_0\theta+\gamma k_0\theta^2=g \tag{15}$$

The effect of the small perturbing term, $\gamma k_0\theta^2$, which makes this a nonlinear equation, may easily be approximated by substituting in it the value of θ previously found. When this is done a linear equation is obtained. A solution for the two time constants is somewhat tedious but is straightforward. To a sufficiently close approximation for these purposes the results are

$$t_{a2}=t_c(1-1.4\gamma\theta_0) \quad t_{b2}=t_c(1-1.5\gamma\theta_0)$$

where the subscript 2 refers to the condition, current switched on, and

$$\theta_0=g/k_0$$

A similar procedure for the equation corresponding to current switched off gives

$$t_{a1}=t_c(1-0.6\gamma\theta_0)$$

and

$$t_{b1}=t_c(1-0.5\gamma\theta_0)$$

Values of about +0.003 might be expected for γ. Thus this effect would cause both time constants to decrease with increasing current, for both directions of the step change (current on and current off), with a greater decrease when current is turned on. Changes of up to 70% should be expected, considerably more than those observed.

In actual converters cooling is chiefly by conduction rather than convection and radiation, so that more complicated equations must be used. In addition some converters, particularly in the ampere ranges, have appreciable temperature coefficients of resistance. Nevertheless, the above approximations give what is believed to be a reasonable semi-quantitative picture of the situation.

◆

Discussion

W. C. Downing, Jr. (Sangamo Electric Company, Springfield, Ill.): Mr. Hermach refers to the use of the 90%-response time in specifying the dynamic characteristics of thermal converters as originating "perhaps because this is easier to measure." It is quite true that the 90% point can be determined much more easily and accurately than the 99% point but the source for this practice, I believe, is in the Code for Electricity Meters, where the time interval of a thermal demand meter is defined as the time required to reach 90% of ultimate reading on a steady load. While a thermal demand meter and a thermal converter have vastly different response times, the response characteristics are quite similar; and it has been natural, therefore, for manufacturers of both types of instruments to apply the same definition of response time.

For the determination of response time of thermal converters for the measurement of watts, we have found the use of a commercially available cathode-ray oscilloscope a straightforward technique that gives quite adequate results. With the oscilloscope set for linear time sweep on the horizontal axis, the converter output is connected, through a d-c preamplifier, to the vertical sweep circuit. By a double pole switch, load is applied to the converter and the time sweep triggered simultaneously. A single sweep is photographed, resulting in a plot, approximately 1 by 1.6 inches, of emf against time. For testing a watt-converter with 90% response in one second, a two second time sweep permits time determination of the 90% point with sufficient accuracy. Incidentally, since the watt-converter is designed for linear output and negligible temperature error, the response characteristic as determined in this manner closely approximates a true exponential curve.

John H. Miller and **John Nagy** (Weston Instruments, Newark, N. J.): The paper by Mr. Hermach in which he discloses the vagaries of the thermal converter with respect to the rising characteristic of its output when a step function of current is applied through the heater, is a valuable addition to the literature. These vagaries have been known for some years but, to the best of our knowledge, have never been delineated in detail. Attempts to state a single figure for the time constant of a thermocouple in simple terms have failed in the past and the reason for such failure is now obvious.

In view of the reported results it becomes quite apparent that no simple single figure will suffice for a statement of the time dependent output of one of these intriguing converting devices.

On the other hand, a simple method would be most desirable if it could be attained within the bounds of a reasonable specification.

Some recent work in the Weston Laboratories along the lines of matching the rise of the output millivoltage to the rise in an RC circuit, as shown in Fig. 4, has resulted in a modified circuit as shown in Fig. 5 of this discussion. Here we have a composite circuit having two superimposed RC networks, the first, R_1C_1, effectively delaying the current flow producing the opposing emf, and the second $(R_1+R_2)C_2$, producing an exponential rise.

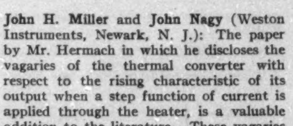

Fig. 5. Double mesh circuit for "bridge" method

To simplify the manipulation, R_3 and R_4, control the steady-state condition and where R_4 is kept low to have negligible effect on the timing circuit. Since the balancing drop in R_4 is usually less than 10 millivolts, it may be typically 1 ohm, so that for a dry cell R_3 is 150 to 1,000 ohms.

In the simple circuit of Fig. 4 of the paper, the balancing voltage of the RC network V_t at time t after the current is turned on, is given by

$$V_t=E\left(1-\epsilon^{\frac{-t}{R_1C}}\right) \tag{16}$$

and R_1C in ohms and farads is the time constant, t_a, for 63% of the change to take place.

In the composite circuit shown in this discussion a solution can be derived using the LaPlace transform method shown in Gardner and Barnes, "Transients in Linear Systems." The solution is

$$V_t=E\left(1+\frac{\Gamma\epsilon^{-\alpha t}-\alpha\epsilon^{-\Gamma t}}{\alpha-\Gamma}\right) \tag{17}$$

The exact values of α and Γ are somewhat complicated, but if R_2 is greater than 10 R_1 as is the case with those thermoelements we have tested in this manner, and if we make $C_1=C_2=C$, then, within 1% we have,

$$\alpha=\left(\frac{1}{R_1}+\frac{1}{R_2}\right)\frac{1}{C} \text{ and } \Gamma=\frac{1}{(R_1+R_2)C} \tag{18}$$

The characteristic time t_c derived in this manner, is, then,

$$t_a = \frac{1}{\alpha} + \frac{1}{\Gamma} = \frac{R_1R_2C}{R_1+R_2} + (R_1+R_2)C \qquad (19)$$

where we may call $1/\alpha$ the delay time, and $1/\Gamma$ the time constant of the exponential rise after the delay.

This can be further simplified, still within 1%, to

$$t_a = (R_2+2R_1)C \qquad (20)$$

In our study we used $C = 1{,}000$ microfarads, and for a typical 2.0-ma thermoelement, using an L&N Type *2430-C* galvanometer, we obtained $R_1 = 50$ ohms and $R_2 = 830$ ohms whereby $t_a = 0.93$ second. The balance obtained was excellent, the excursions each side of zero being less than 1/10 as much as with the simple circuit. The value given for t_a is for rated heater current turned "on." As shown by Hermach, different values were obtained for current turned "off," and still different values were obtained for other values of heater current.

In view of the findings reported in the paper and our own work, it is suggested that specifications for thermal converters must necessarily include the items listed in the following

For steady-state conditions, the following should be given:

1. Rated heater current, with tolerance, to produce rated millivolt output, measured on open circuit.
2. Resistance of heater, with tolerance, at current to produce rated millivolt output.
3. Resistance at output terminals of thermocouple with tolerance, when producing rated millivolt output.

When a specification for the output millivolt rise or delay time is a requirement, in addition to the foregoing, it is necessary to state the following items:

1. Environment, that is, ambient temperature and kind of enclosure, if any, of the thermoelement. Preferably the final form of mounting and enclosure should be used in making the test.
2. Are the data to be taken with current applied or removed?
3. State value of heater current.
4. State required percentage of steady state output millivolts increase or decrease, for heater current value used, for which elapsed time is required.

We feel that the term "characteristic time" used for the value of the time for 63% change in response has considerable merit and would urge that this term be used wherever appropriate. When values for the 90% or 99% change of response are required instead of this characteristic time, they should be so stated in the specification.

It is hoped that further consideration of these several factors may result in reasonable uniformity of specifications having to do with these converting elements to the end that their makers and users speak the same language.

F. L. Hermach: The information given by Mr. Downing regarding response time is appreciated. Since there is some precedent for it, and since it is much easier to measure, the 90% response time should probably ordinarily be specified rather than the time for 99% response.

Mr. Downing shows that a cathode-ray oscillograph is also satisfactory and convenient for measuring the 90% response time. The paper should have emphasized that any oscillographic method of suitable accuracy may be used to measure both t_a and response time, but not (directly at least) t_b.

The information given by Mr. Miller and Mr. Nagy is most interesting. We have also observed in our tests the small delay in the change of response of thermal converters. This delay requires that the true starting time be determined by some suitable marker on the oscillogram when an oscillographic method is used. The very small excursions of the ballistic galvanometer indicate that their double *RC* method can be used to measure the characteristic time t_a. As Miller and Nagy indicate, the complex formula for t_a becomes remarkably simple if $C_1 = C_2$ and $R_2 > 10R_1$.

The definite specifications given by Miller and Nagy should completely eliminate the present ambiguities pertaining to both the steady-state and dynamic characteristics of thermal converters. It is suggested that rated heater current suddenly applied (current on) be considered the standard test condition for 2 and 3 of their specifications for the transient test.

Minimization of Components in Electronic Switching Circuits

T. J. BEATSON
ASSOCIATE MEMBER AIEE

SWITCHING CIRCUIT SYNTHESIS presents two basic problems to the engineer. First, he must be able to obtain a circuit which will function according to the input-output specifications. Second, the circuit must be economical in the use of switching components, whether they are transistors, diodes, vacuum tubes, or relay contacts.

The first problem can always be solved. If the input-output specifications are in the form of a table of combinations, by treating one output at a time each output can be expressed as a Boolean function of the inputs. The Boolean function can then be translated into a circuit which will perform according to the given specifications. In most cases such a superficial treatment results in a circuit containing many unneeded circuit elements.

The distinction between different Boolean functions and different algebraic forms of the same Boolean function must be recognized. It is possible to manipulate a Boolean function into many different algebraic forms without changing the actual function. For every algebraic form of a function there is a corresponding circuit realization in the sense that the algebra describes the interconnection of circuit elements. Therefore the problem under consideration may be stated as follows: Given a Boolean function, find an algebraic form of this function, the circuit realization of which requires a minimum number of circuit components.

In this paper, minimization is considered only for those circuits in which diodes or transistors are used as switching elements. (The number of resistors required is not taken into account.) The treatment required for vacuum-tube circuits would be somewhat more complex because of the relatively large voltage drop between the plate and cathode and the resultant circuit limitations. The analysis presented here could be modified for use with relay contact circuits, but such a treatment would ignore the possibility of bridge circuits.

Circuit Realization

In electronic switching circuits nodal voltage is used as the characteristic property. The voltage at a given node is either high (1), or low (0), as determined by the current flowing into the node through a resistance connected to the supply voltage. Some typical diode and transistor switching circuits which are

Paper 58-3, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted July 26, 1957; made available for printing October 10, 1957.

T. J. BEATSON is with the General Electric Company, Palo Alto, Calif.

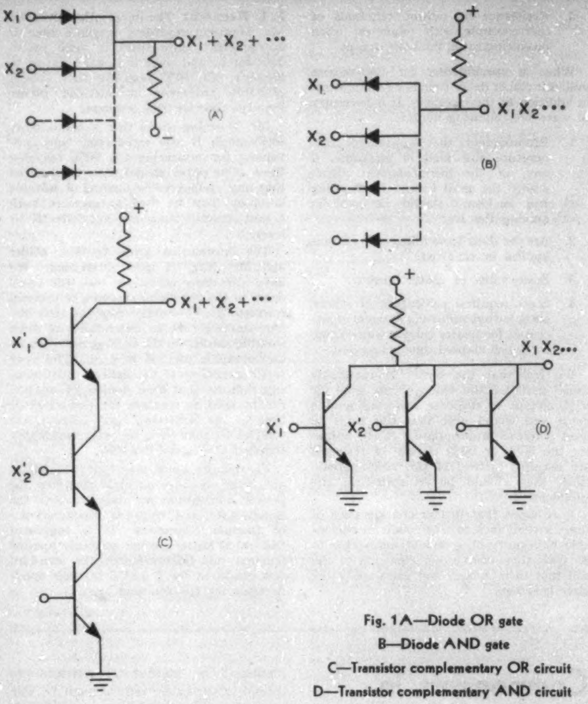

Fig. 1A—Diode OR gate
B—Diode AND gate
C—Transistor complementary OR circuit
D—Transistor complementary AND circuit

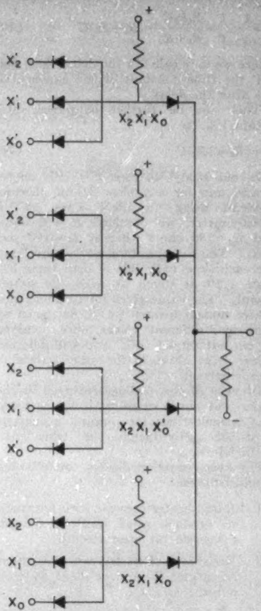

Fig. 2. Diode circuit corresponding to equation 1

operated by positive-going inputs are shown in Fig. 1. Either the diode gates of Fig. 1(A) or (B), or the transistor circuits of (C) or (D) may be cascaded, with the use of suitable voltage dividers, in order to construct the logic for a particular Boolean function.

Switching circuits, both combinational and sequential, are commonly specified by means of a table of combinations as shown in Table I. Each row of the table of combinations corresponds to a set of input states which must exist simultaneously in order that the output may have the indicated state. Every row of the table of combinations represents a different set of input states and the corresponding output state.

Table I. Table of Combinations

Inputs			Output
X_2	X_1	X_0	f
0	0	0	1
0	0	1	0
0	1	0	0
0	1	1	1
1	0	0	0
1	0	1	0
1	1	0	1
1	1	1	1

Let it be required to obtain a diode circuit having the logical structure of Table I. The Boolean function describing the logic of Table I is

$$f = X_2'X_1'X_0' + X_2'X_1X_0 + X_2X_1X_0' + X_2X_1X_0 \quad (1)$$

Without performing any algebraic manipulations of equation 1 the diode circuit corresponding to equation 1 may be constructed from the gates shown in Fig. 1(A) and (B). The resulting circuit is shown in Fig. 2.

If it is recognized that the last term equation 1 can be included in the function twice without altering the function, then equation 1 can be simplified by combining the second and fourth terms, and the third and fourth terms according to the theorems of Boolean algebra. Equation 2 is the result of this simplification.

$$f = X_2'X_1'X_0' + X_1X_0 + X_2X_1 \quad (2)$$

The diode circuit corresponding to equation 2 may be constructed in a manner similar to that used for Fig. 2. The result is shown in Fig. 3. This algebraic manipulation has resulted in a saving of six diodes, since both Figs. 2 and 3 represent different forms of the same function.

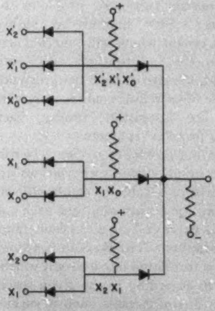

Fig. 3. Diode circuit corresponding to equation 2

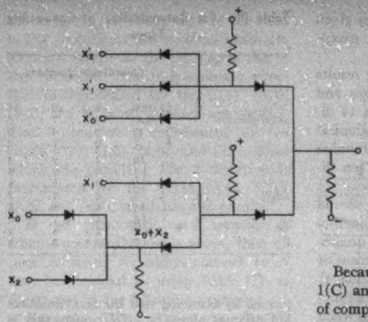

Fig. 4. Diode circuit corresponding to equation 3

Equation 2 may be further simplified by factoring X_1 from each of the last two terms, as shown in equation 3.

$$f = X_2'X_1'X_0' + X_1(X_0+X_2) \tag{3}$$

The circuit representing equation 3 is shown in Fig. 4, revealing an additional saving of one diode.

In each of the circuits of Figs. 2, 3, and 4, the number of diodes required is equal to the sum of the number of factors and the number of terms in the corresponding form of the Boolean function. In Fig. 4 and equation 3, for example, there are five factors and four terms as follows:

Factors	Terms
X_2'	$X_2'X_1'X_0'$
X_1'	$X_1(X_0+X_2)$
X_0'	X_0
X_1	X_2
(X_0+X_2)	

Although the foregoing example is by no means a proof of the fact, a given form of a Boolean function can always be realized as a diode circuit in which the number of diodes required is equal to the sum of the total number of factors and the total number of terms in the given form of the Boolean function. Table I may be realized as transistor circuits by following analogous reasoning with Fig. 1(C) and (D), with one additional step.

The circuit realization of the various terms and factors in a given form of a Boolean function may be systematically broken down into a number of stages. Thus in the first stage of equation 1 the individual terms are realized by taking various products of input variables. In the second stage of equation 1 the function is obtained by adding the various terms produced in the first stage. The outputs from the first stage are considered as inputs to the second stage.

Because the transistor circuits of Fig. 1(C) and (D) have the inherent property of complementing the input variables, it is necessary to take the complement of the variables at the inputs to every other stage in the algebraic form. In general, if the algebraic form consists of more than two stages (equation 3, for example) the following rule applies for the realization of transistor circuits:

> If the number of stages in an algebraic form of a Boolean function is even, then the inputs to all even-numbered stages must be complemented, along with the outputs from all odd-numbered stages. If the number of stages is odd, then the terms "odd" and "even" in the preceding statement should be interchanged.

Fig. 5 shows a transistor circuit obtained from the algebraic form of equation 3. Note the similarity between Figs. 4 and 5. Fig. 5 and equation 3 also illustrate the fact that a given form of a Boolean function can always be realized as a transistor circuit in which the number of transistors required is equal to the sum of the total number of factors and the total number of terms in the given form of the Boolean function. Therefore, for circuit realization using diodes or transistors the "minimal" algebraic form of any Boolean function is that form in which the total number of terms and factors is a minimum.

Boolean Algebra and Canonical Forms

Every Boolean function may be written in two different standard, or canonical, forms. These canonical forms serve as a convenient starting point for minimization since they may be readily obtained from a table of combinations.

The first canonical form of a Boolean function consists of a sum of terms and each term consists of a product of all variables, either primed or unprimed. Thus equation 1 is the first canonical

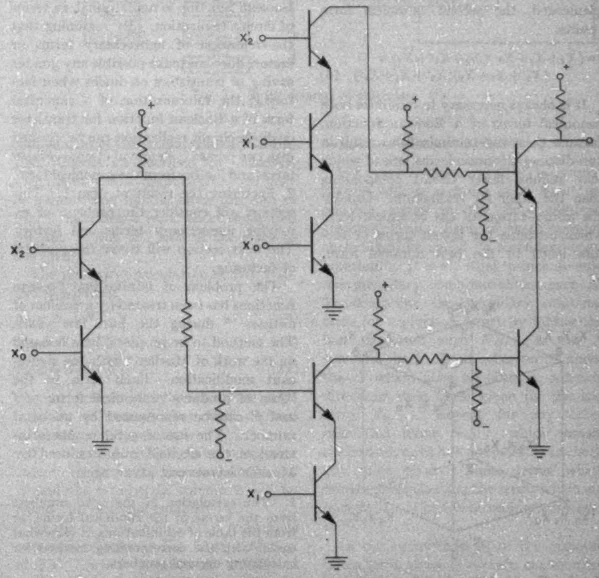

Fig. 5. Transistor circuit corresponding to equation 3

Table II. Table of Combinations

Inputs				Output
X_3	X_2	X_1	X_0	f
0	0	0	0	0
0	0	0	1	1
0	0	1	0	1
0	0	1	1	0
0	1	0	0	1
0	1	0	1	1
0	1	1	0	1
0	1	1	1	0
1	0	0	0	0
1	0	0	1	1
1	0	1	0	1
1	0	1	1	0
1	1	0	0	0
1	1	0	1	0
1	1	1	0	0
1	1	1	1	0

form of the Boolean function which represents the logic of Table I.

The second canonical form of a Boolean function consists of a product of factors, and each factor consists of a sum of all variables, either primed or unprimed. Again using the example of Table I, the second canonical form can be obtained by first writing the complement of the function (corresponding to the rows of Table I for which $f=0$) as in equation 4.

$$f'=X_2'X_1'X_0+X_2'X_1X_0'+X_2X_1'X_0'+X_2X_1'X_0 \quad (4)$$

When both sides of equation 4 are complemented, the second canonical form results.

$$f=(X_2+X_1+X_0')(X_2+X_1'+X_0)(X_2'+X_1+X_0)(X_2'+X_1+X_0') \quad (5)$$

It is always necessary to minimize both canonical forms of a Boolean function, because these two minimizations result in two distinct algebraic forms, one of which may require fewer circuit components than the other for realization. Usually the minimization of the canonical form which contains the fewest terms or factors leads to the best minimal form.

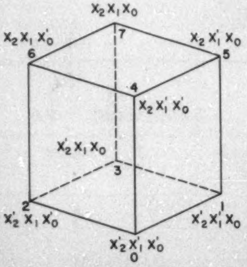

Fig. 6. Graphical representation of connections

However, the table of combinations given in Table II shows that there are exceptions to this rule.

The first canonical form which results from Table II contains seven terms and cannot be realized with less than 14 diodes or transistors. The second canonical form resulting from Table II contains nine factors and can be realized with ten diodes or transistors.

Any minimization applied to the second canonical form of a Boolean function (such as equation 5) can also be accomplished by minimizing the complement of the second canonical form (equation 4) since these two forms of the Boolean function are duals. This fact is useful when further minimization by factoring is attempted. For example, it is somewhat easier to factor equation 6

$$X_4X_3'X_2X_0'+X_4X_2X_1X_0 = X_4X_2(X_3'X_0'+X_1X_0) \quad (6)$$

than it is to factor the dual expression given by equation 7

$$(X_4'+X_3+X_2'+X_0)(X_4'+X_2'+X_1'+X_0') = X_4'+X_2'+(X_3+X_0)(X_1'+X_0') \quad (7)$$

Minimization of Canonical Forms Without Factoring

In general a canonical form of a Boolean function is nonminimal, in terms of circuit realization. By reasoning that the retention of unnecessary terms or factors does not make possible any greater saving of transistors or diodes when factoring, the minimization of a canonical form of a Boolean function for transistor or diode circuit realization can be divided into two parts: 1. Removal of unnecessary terms and factors from the canonical form. 2. Factoring the result of item 1. This section will consider the problem of removing unnecessary terms and factors. The next section will cover the problem of factoring.

The problem of minimizing Boolean functions has been treated by a number of authors[1–6] during the past few years. The method to be proposed here is based on the work of Mueller,[4] with one significant modification. Each term in the "sum of products" canonical forms of f and f' can be represented by an octal number. The use of octal numbers instead of the decimal numbers used by Mueller[4] has several advantages:

1. The calculation of the octal numbers from the terms of the canonical forms, or from the table of combinations, is somewhat easier than the corresponding method for calculating decimal numbers.

2. The necessary arithmetic calculations involving the octal numbers may be performed by assuming that the octal numbers are decimal numbers. (Of course, this is not true in general, but only for this particular numbering system and for the particular arithmetic calculations required by this method.)

3. A possible source of error in the decimal method arises because there is uncertainty as to whether to add or subtract a power of two from any given decimal number. This uncertainty is overcome in the octal method by referring to a short tabulation which contains all of the necessary information.

Table III. For Determination of Connecting Terms

		Co-ordinate Numbers		
Digit position	1,000	9	10	11
	100	6	7	8
	10	3	4	5
	1	0	1	2
Digit	0	1	2	4
	1	0	3	5
	2	3	0	6
	3	2	1	7
	4	5	6	0
	5	4	7	1
	6	7	4	2
	7	6	5	3

To calculate the octal number representation for a given term in the canonical form the variables in the term are first partitioned into sets of three. Each such set will determine one of the octal digits. All primed variables are given a weight of 0, while all unprimed variables are given a weight of 4, 2, or 1, depending on the position of the variable within the set.

Example: The octal number representing the term $X_7X_6X_5X_4X_3'X_2'X_1X_0'$ from a canonical form involving eight variables is obtained as follows:

Variables	X_7X_6	$X_5X_4X_3'$	$X_2'X_1X_0'$
Weights	2 1	4 2 0	0 2 0
Sums of weights	3	6	2

Thus the octal number 362 represents this term.

If two terms in a canonical form of a Boolean function are identical except for one variable (in general, the *i*th variable), it is possible to write the sum of these two terms as a single term. For example:

$$X_2X_1'X_0+X_2X_1X_0=X_2X_0 \quad (8)$$

Under these circumstances the two terms in question are said to be connected along the *i*th co-ordinate. Thus the two terms in equation 8 are connected along the 1st co-ordinate.

When the number of variables is five or less, it is possible to illustrate the connections between terms graphically. For three variables the terms can be considered as the vertexes of a cube, as shown in Fig. 6. Each edge of the cube in Fig. 6 connects two vertexes which are identical except for the priming of one of the variables. The 0 co-ordinate direction is represented by the (0,1), (2,3), (4,5), and (6,7), all of which are parallel. The 1 direction is represented by the edges (0,2), (1,3), (4,6), and (5,7), all of which are parallel. The 2 direction is represented by the edges (0,4), (1,5), (2,6), and (3,7), which are also parallel.

If one term with octal number N from a canonical form is given, then all possible terms N_i which connect to N may be obtained by using Table III, as illustrated in the following example:

Example: Given the term $N=362$ (octal) from a canonical form involving eight variables. Determine the eight terms which can be connected to 362. Those terms connected to 362 along co-ordinate directions 0, 1, and 2 are obtained by changing only the least significant digit of 362. This is indicated at the top of Table III. Since the least significant digit of 362 is 2, Table III shows that 2 should be changed to 3, 0, and 6. Thus in the 0, 1, and 2 co-ordinate direction 362 is connected to

$N_0=363/0$
$N_1=360/1$
$N_2=366/2$

Here the number to the left of the slant line is the octal number to which N is connected, and the number to the right of the slant line indicates the co-ordinate direction of the connection.

In the 3, 4, and 5 directions Table III indicates that the digit 6 in 362 should be changed to 7, 4, and 2. Thus 362 is also connected to

$N_3=372/3$
$N_4=342/4$
$N_5=322/5$

In the 6 and 7 directions Table III indicates that the digit 3 in 362 should be changed to 2 and 1. Thus 362 is also connected to

$N_6=262/6$
$N_7=162/7$

Mueller[4] has shown that an irredundant "sum of products" form of a Boolean function may be obtained from the first canonical form of the function by performing a series of simple arithmetic operations on the numbers which represent the terms of the canonical form. It should be clear that since the complement of the second canonical form of a given Boolean function is also the first canonical form of the complement of the given Boolean function this procedure may be applied to both the first canonical form and the complement of the second canonical form. The procedure described by Mueller, with the previously indicated change, may be summarized by the block diagram of Fig. 7, in which a work sheet with two columns at the left side of the sheet is assumed.

The numerical calculation of N_{ij}, N_{ijk}, and N_{ijkl}, from

$$N_{ij}=N_i+N_j-N \tag{9}$$

$$N_{ijk}=N_{ij}+N_k-N \tag{10}$$

$$N_{ijkl}=N_{ijk}+N_l-N \tag{11}$$

may be performed by treating the octal numbers as though they were decimal numbers; see Appendix I.

For those N which have a number entered in column 2 the combination of N and the number in column 2 will be called "an essential combination."

At the bottom of Fig. 7 it is sometimes necessary to refer to Fig. 8, an extension of Fig. 7 which requires no additional work sheet. Equations 9, 10, and 11 may be generalized so that

$$N_{ijklm\ldots rs}=N_{ijklm\ldots r}+N_s-N \tag{12}$$

For every N which has a (—) in column 2 there will be a choice of at least two possible terms in the final minimal algebraic form. Each of these possible choices will be called "a secondary combination." It is essential to include only one secondary combination for each N. To determine the secondary combinations for a given N, start by taking the last calculated term $N_{ij}\ldots$ in the N row and check off all other terms under this N which have no other co-ordinate directions than those given for the last term $N_{ij}\ldots$. Repeat for any other calculated terms $N_{pq}\ldots$ which remain unchecked, until it is not possible to check any more terms. Those terms which remain unchecked are the terms which are opposite to N in the secondary combinations.

In the event that all of the opposite terms for a given N contain one or more common co-ordinate directions, then an x should be placed in column 2 opposite

all of the calculated terms having only these common co-ordinate directions.

The collection of all essential combinations and all secondary combinations corresponds to the prime implicants of Quine.[2] The selection of a minimal set of secondary combinations which, together with all of the essential combinations, corresponds to the selection of a minimal set of prime implicants, may be accomplished by using a procedure developed by McCluskey[6] and will be illustrated later. However, instead of forming a complete prime implicant table as described by McCluskey, it is necessary only to form a table consisting of secondary combinations and those N which are marked with a (−).

After all of the essential combinations and a minimal set of secondary combinations have been determined, the minimal algebraic form which results from the particular canonical form being considered may be constructed as follows:

For each combination, essential or secondary, write down the algebraic term corresponding to N from the canonical form. Eliminate from this term all of the variables which have subscripts corresponding to the co-ordinate direction numbers of the opposite term or term listed in column 2. The resulting term must appear in the minimal unfactored algebraic form of the original function. The following example illustrates the application of this procedure:

Example: Find the minimal unfactored forms of the function f, specified in Table II. The octal term numbers for the function f are determined by inspection of Table II. They are 1, 2, 4, 5, 6, 11, and 12.

Starting with the first number in this list, the numbers of those terms which connect to 1 are determined. Table III indicates that 1 is connected to 0, 3, and 5 in the 0, 1, and 2 directions respectively. The second digit of the number 1 (or 01) is 0, which Table III indicates should be changed to a 1, 2, or 4. Since this problem is concerned with only four variables, those octal numbers from 0 to 17 are of interest. Thus 1 is connected to 11 in the 3 direction. The connection may be summarized as follows: 0/0, 3/1, 5/2, 11/3. Now, it may be seen that 0 and 3 do not appear in column 1 of Fig. 9, so these must be crossed off the list of connections to 1. Now, with two connections remaining uncrossed equation 9 yields

$$N_{23} = N_2 + N_3 - N = 5 + 11 - 1 = 15 \qquad (13)$$

Listed with the other connections is 15/23; also note that 15 does not appear in column 1 of Fig. 9 and therefore 15 must be crossed off the list of connections to 1. Proceeding in the same manner for the remaining terms in column 1, Fig. 9 is obtained.

Thus there are two essential combinations of terms from the first canonical form, namely, (11,1) and (12,2). Three terms are marked with (−) and herefore a minimal set of secondary combinations must be selected. This is done following the procedure outlined by McCluskey.[6] It is noted first that there are four possible secondary combinations: (4,5), (4,6), (5,1), and (6,2). Each of these secondary combinations corresponds to the replacement of two terms in the canonical form by a single term with one less variable. A subset of these four secondary combinations must be chosen so that each of the terms 4, 5, and 6 from the canonical form is included in at least one of the chosen secondary combinations. To help accomplish this, a table of secondary combinations is formed as shown in Fig. 10. At the left of this

col. 1	col. 2					
1	x	~~0/0~~	~~3/1~~	5/2	11/3	~~15/23~~

Fig. 10. Table of secondary combinations

table are listed the secondary combinations. The (—) terms are listed across the top of the table. The x's in the table indicate those columns which are included in each of the secondary combinations. A subset of rows from Fig. 10 must be chosen so that each column contains at least one x. For a small table of secondary combinations, such as Fig. 10, the calculus of propositions may be used to determine the minimal sets of secondary combinations, which will be denoted by g. As shown in Fig. 10 the rows will be denoted by A, B, C, and D. Thus the 4 column is covered by A or B, the 5 column is covered by A or C, and the 6 column is covered by B or D.

$$g=(A+B)(A+C)(B+D) \qquad (14)$$

When equation 14 is multiplied out the result is

$$g=AB+AD+BC \qquad (15)$$

Thus the three columns of Fig. 10 are covered by rows A and B, or rows A and D, or rows B and C. Since each of these coverings involves the same number of secondary combinations, any one of them can serve as the minimal set of secondary combinations. Reconstructing the terms which correspond to the essential and secondary combinations results in Fig. 11.

11,1 —— $\cancel{X_3}X_2'X_1'X_0$ —— $X_2'X_1'X_0$
12,2 —— $\cancel{X_3}X_2'X_1X_0'$ —— $X_2'X_1X_0'$
4,5 —— $X_3'X_2X_1'\cancel{X_0}$ —— $X_3'X_2X_1'$
4,6 —— $X_3'X_2\cancel{X_1}X_0'$ —— $X_3'X_2X_0'$
1,5 —— $X_3'\cancel{X_2}X_1'X_0$ —— $X_3'X_1'X_0$
2,6 —— $X_3'\cancel{X_2}X_1X_0'$ —— $X_3'X_1X_0'$

Fig. 11. Reconstructed terms corresponding to essential and secondary combinations

Thus three minimal unfactored forms of the function f are

$$f=X_2'X_1'X_0+X_2'X_1X_0'+X_3'X_2X_1'+X_3'X_2X_0' \qquad (16A)$$

$$f=X_2'X_1'X_0+X_2'X_1X_0'+X_3'X_2X_1'+X_3'X_1'X_0 \qquad (16B)$$

$$f=X_2'X_1'X_0+X_2'X_1X_0'+X_3'X_2X_0'+X_3'X_1X_0' \qquad (16C)$$

To consider the minimization of the second canonical form of f, the octal term numbers for f' are determined by inspection of Table II, and are listed in column 1 of Fig. 12.

Since the essential combinations are discovered before reaching 7, 10, 13, 16, or 17, no calculation is necessary for these numbers. Thus f' consists entirely of essential combinations and no table of secondary combinations is necessary. Reconstructing the minimal form results in Fig. 13. Thus

$$f'=X_2'X_1'X_0'+X_1X_0+X_3X_2 \qquad (17)$$

and

$$f=(X_2+X_1+X_0)(X_1'+X_0')(X_3'+X_2') \qquad (18)$$

Factoring

Although no systematic method is known of factoring Boolean functions to yield the minimal algebraic form, circuit components may be conserved by recognizing common factors when they appear in the minimal unfactored form of a Boolean function. For example, by recognizing that X_1 was a common factor in two terms of equation 2, the factored form given by equation 3 was written, with the resultant saving of one diode or transistor.

0,10 —— $\cancel{X_3'}X_2'X_1'X_0'$ —— $X_2'X_1'X_0'$
3,17 —— $\cancel{X_3'}\cancel{X_2'}X_1X_0$ —— X_1X_0
15,16 —— $X_3X_2\cancel{X_1}X_0$ —— X_3X_2

Fig. 13. Reconstruction of minimal form

As shown in Appendix II, the saving s in the number of diodes or transistors which is achieved by any given factoring operation may be determined from

$$s=(r-1)p+k-2 \qquad (19)$$

where r is the number of terms which contain the common factor, p is the number of variables in the common factor, and k is the number of terms containing the common factor with only one additional variable. It is assumed that r is not equal to the total number of terms in the function. For any practical case, $r\geq 2$, $p\geq 1$, $k\geq 0$. Therefore the only practical case in which s will be negative (meaning that factoring increases the number of components required) is when $(r,p,k)=(2,1,0)$. Hence when one variable is a common factor in two terms, both of which contain at least three variables, this common factor should not be factored.

Re-examining equation 2, it may be seen that X_1 is a common factor in two terms, each of which contains only one additional variable. Thus in this case, $(r,p,k)=(2,1,2)$. Substituting these values in equation 19 yields the result $s=1$.

If more than one factoring operation upon the minimal unfactored form of a Boolean function is possible, it becomes necessary to determine the order in which the factoring operations should be performed. No satisfactory process for the solution to this problem is known except for the cut-and-try process.

Consider the following function:

$$f=X_4'X_3X_2X_1'X_0'+X_4'X_3X_2X_1X_0+X_4X_3'X_2'X_1X_0+X_4X_3X_2'X_1'X_0'+X_4X_3X_2X_1'X_0+X_4X_3X_2X_1X_0' \qquad (20)$$

One possible way of factoring equation 20 is shown in equation 21.

$$f=X_3[X_2(X_4'X_1'X_0'+X_4'X_1X_0+X_4X_1'X_0+X_4X_1X_0')+X_4X_2'X_1'X_0']+X_4X_3'X_2'X_1X_0 \qquad (21)$$

To obtain equation 21 two successive factoring operations are performed.

col. 1	col. 2							
0	10	~~1/0~~	~~2/1~~	~~4/2~~	10/3			
3	17	~~2/0~~	~~1/1~~	7/2	13/3	17/23		
7	x							
10	x							
13	x							
14	x	15/0	16/1	10/2	~~4/3~~	17/01	~~11/02~~	~~12/12~~

16	x							
17	x							

Fig. 12. Determination of second unfactored minimal form of Table II

First, $(r,p,k)=(5,1,0)$, from which $z=2$. Then $(r,p,k)=(4,1,0)$, from which $z=1$. Thus the total saving for this sequence of factoring operations is $2+1=3$.

Another possible way of factoring equation 20 is shown in equation 22.

$$f=X_4X_3(X_2'X_1'X_0'+X_2X_1'X_0+X_2X_1X_0')+X_4'X_3X_2(X_1'X_0'+X_1X_0)+X_4X_3'X_2'X_1X_0 \quad (22)$$

Here the two factoring operations were $(r,p,k)=(3,2,0)$, from which $z=2$, and $(r,p,k)=(2,3,0)$, from which $z=1$. Therefore the total savings in components is again $2+1=3$.

Still another way of factoring equation 20 is shown in equation 23.

$$f=X_3X_2(X_4'X_1'X_0'+X_4'X_1X_0+X_4X_1'X_0+X_4X_1X_0')+X_4X_3'X_2'X_1X_0+X_4X_3X_2'X_1'X_0' \quad (23)$$

Here the single factoring operation performed was $(r,p,k)=(4,2,0)$, from which $z=4$. Thus equation 23 appears to represent the minimal factored form of equation 20.

Summary

The circuit having a minimum number of diodes or transistors, and representing the logic of a given table of combinations, may be obtained as follows:

1. From the table of combinations obtain both the first canonical form and the complement of the second canonical form of the Boolean function.
2. Eliminate redundant terms and factors from each of these forms by following the procedure outlined in the section "Minimization of Canonical Forms Without Factoring."
3. Remove common factors from each of the forms as indicated in the section "Factoring."
4. Count the total number of terms and factors in each of the two resulting forms and select that form of the Boolean function for which this count is a minimum.
5. Synthesize a circuit having the logic of the form of the Boolean function selected as the minimal form. (If this minimal form has been obtained from the complement of the second canonical form then the minimal form must be complemented before synthesizing the circuit.)

Appendix I. Manipulation of the Digits of Octal Numbers as Decimal Digits

Let A be a number. Then the digits of the octal representation of A are given by

$$A=A_{n-1}8^{n-1}+A_{n-2}8^{n-2}+\ldots+A_18^1+A_0 \quad (24)$$

Let equation 24 now be written as

Table IV. Conditions for Addition and Subtraction of Powers of 2

n	1	2	4
0	+1	+2	+4
1	−1	+2	+4
2	+1	−2	+4
3	−1	−2	+4
4	+1	+2	−4
5	−1	+2	−4
6	+1	−2	−4
7	−1	−2	−4

$$A=A_{n-1}10^{n-1}-A_{n-1}(10^{n-1}-8^{n-1})+A_{n-2}10^{n-2}-A_{n-2}(10^{n-2}-8^{n-2}+\ldots) \quad (25)$$

Rearranging equation 25

$$A=A_{n-1}10^{n-1}+A_{n-2}10^{n-2}+\ldots+A_110^1+A_0-A_{n-1}(10^{n-1}-8^{n-1})-A_{n-2}(10^{n-2}-8^{n-2})-\ldots-A_1(10^1-8^1) \quad (26)$$

It may now be seen that the quantity

$$\sum_{i=0}^{n-1}A_i(10^i-8^i) \quad (27)$$

represents the error which results when the digits of the octal representation of A are treated as though they were the decimal digits of another number A'.

Now let x, a, b, and c be numbers which satisfy the equation

$$x=a+b-c \quad (28)$$

It will be assumed that the octal representations of x, a, b, and c each consist of n digits. If the digits of the octal representations of a, b, and c are treated as though these digits were decimal digits then the resulting error on the right side of equation 28 will be

$$\sum_{i=0}^{n-1}(a_i+b_i-c_i)(10^i-8^i) \quad (29)$$

where a_i, b_i, and c_i are the octal digits of a, b, and c.

If instead the octal representations of a, b, and c are treated correctly as octal numbers, then the octal digits of x will be given by

$$\begin{aligned}
x_0&=a_0+b_0-c_0-8p_0\\
x_1&=a_1+b_1-c_1+p_0-8p_1\\
x_2&=a_2+b_2-c_2+p_1-8p_2 \qquad (30)\\
&\vdots\\
x_{n-1}&=a_{n-1}+b_{n-1}-c_{n-1}+p_{n-2}-8p_{n-1}\\
x_n&=p_{n-1}
\end{aligned}$$

In equation 30 p_i denotes the carry from the ith digit to the $(i+1)$th digit. Now, if the resulting octal digits of x are treated as though they are decimal digits then the resulting error in x will be

$$\sum_{i=0}^{n}x_i(10^i-8^i) \quad (31)$$

The x_i in equation 31 are the octal digits of x given by equation 30.

If the expressions in equations 29 and 31 are equal, no actual error results from treating the octal digits of a, b, and c as decimal digits instead of octal digits. Inspection of equations 29, 30 and 31 shows that if $p_i=0$ for all i, then equations 29 and 31 will be equal.

It now remains to be shown that for the octal representation of the numbers N_i, N_j, and N in equation 9

$$N_{ij}=N_i+N_j-N \quad (9)$$

there is no carry between digits ($p_i=0$). This means that

$$0\leq(a_i+b_i-c_i)\leq7 \quad \text{for } 0\leq i\leq n-1 \quad (32)$$

From the manner in which N_i and N_j are obtained from N by means of Table III it is evident that

$$N_i=N\pm2^i \quad (33)$$

In equation 33 the plus sign will apply if the expansion of N into powers of 2 does not contain 2^i. If the expansion of N does contain 2^i then the minus sign is used in equation 33. Similar considerations apply to the plus or minus signs used with N_j. Thus equation 9 may be written as

$$N_{ij}=N\pm2^i\pm2^j \quad (34)$$

In the octal system the powers of 2 are 1, 2, 4, 10, 20, 40, 100, 200, 400, etc. For any particular digit, n, of the octal representation of N this means that the only numbers which will be added to or subtracted from n are 0, 1, 2, or 4. Table IV shows the conditions for addition and subtraction of powers of 2 for any digit value n. This table also shows that for any possible digit n it will be impossible to add or subtract powers of 2 in such a way as to cause a carry to occur. Therefore no error results from treating the digits of the octal numbers in equation 9 as though they were decimal digits. By extending equation 28 it is possible to prove similar results applying to equations 10 and 11.

Appendix II. Saving of Components by Factoring

Assume that an unfactored Boolean function consisting of a sum of products is given. Let

s = number of terms in the Boolean function
m_i = number of variables in the ith term
q = number of terms in which $m_i=1$
r = number of terms containing a particular common factor
p = number of variables in the common factor
k = number of terms containing the common factor and for which $m_i=p+1$
x = number of terms plus the number of factors in the unfactored form of Boolean function
y = number of terms plus the number of factors in the factored form of the Boolean function
$z=x-y$ = saving of components due to factoring

Because the individual terms of the unfactored function may be arranged in any order, they can be arranged so that the first r terms contain the common factor. Then

$$x=(s-q)+\sum_{i=1}^{s}m_i \quad (35)$$

$$y=(s-q-r)+\sum_{i=r+1}^{s} m_i+(p+1)+r+\sum_{i=1}^{r}(m_i-p)-k+1 \quad (36)$$

$$z=x-y=(r-1)p+k-2 \quad (37)$$

Discussion

Oscar Lowenschuss (Sperry Gyroscope Company, Sperry Rand Corporation, Great Neck, N. Y.): The paper contains two significant contributions: the minimization of canonical forms with the use of octal number representation, and a discussion of factoring and its resulting circuit economies.

The minimization of canonical forms with the use of octal numbers appears to offer several advantages over Mueller's decimal method, and over the ternary number method of Harris,[1] which was not mentioned in the paper. The discussion of factoring leads to an important relation, indicating possible component savings resulting from various methods of factoring. Unfortunately, Mr. Beatson's method does not, in general, lead to the most economical transistor circuit; in fact, his examples do not represent minimal circuits. Thus, if his equation 23 is written as

$$f=X_3X_2[X_4+(X_1X_0+X_1'X_0')][X_4'+(X_1X_0+X_1'X_0')']+X_2'X_4(X_3+X_1X_0)(X_3'+X_1'X_0') \quad (38)$$

the resulting circuit requires only 27 transistors instead of the 32 he mentions.

The factoring methods of Mr. Beatson use only the Boolean connectives "union" (inclusive or) and "intersection"; the "prime" (complement) has not been used. However, the prime, together with the "implicit function" concept, can lead to a more economical circuit realization, as shown by equation 38. It might be argued that the prime cannot be realized with diodes; however, it may be realized with a single transistor.

Implicit functions may be defined as follows: If a Boolean function $G(y_1, y_2, \ldots y_n)$ can be substituted into a given function $f(X_1, X_2, \ldots X_m, y_1, y_2, \ldots y_n)$ so that the function $F[X_1, X_2, \ldots X_m, G(y_1, y_2, \ldots y_n)]$ is equivalent to the given function f, then G represents an implicit function of f. Implicit functions may be detected by examining truth tables using a method due to Ashenhurst[2] or by "partial differentiation" by the method of Akers.[3] Thus in equation 33 the implicit function is

$$G(X_0,X_2)=X_0+X_2 \text{ and}$$
$$f(X_0,X_1,X_2)=f[X_1,G(X_0,X_2)]=X_1G(X_0,X_2)+X_1'G'(X_0,X_2)$$

It is noted that implicit functions provide circuit economies in a single-output switching circuit only if the implicit function appears in both primed and unprimed form. (In multiple-output switching circuits, the implicit function can provide a "kernel" that may help to minimize the entire circuit, even if it appears only in unprimed form.) Hence, one attempts to factor the given function f in one of the two forms

$$f=aG+bG'+c$$

or

$$f=(d+G)(e+G')h$$

where the letters a, b, c, d, e, and h represent variables, or functions of variables, provided only that any variables in G do not appear in a, b, c, d, e, or h. If G is a function of two or more variables, then a saving of circuit components is possible.

Minimization of switching circuits may now be divided into three parts:

1. Removal of unnecessary terms and factors from the canonical form, by the method given in this paper or equivalent methods.
2. Searching for an implicit function that appears in both primed and unprimed form, and contains at least two variables.
3. Factoring the result of item 2.

The author implies the following important result that when transistors are used to synthesize a switching circuit, the transistor configuration is essentially identical to the diode-gate configuration (except for the priming of certain input variables), as shown by a comparison of Figs. 4 and 5. It should be pointed out that the following restrictions must be observed:

1. If the complementary OR circuit, Fig. 1(C), is used exclusively, the transistor configuration is similar to the diode configuration only if the diode configuration ends in an OR gate, i.e., if the function has been factored in the first canonical form (sum of products). If the function has been factored in the second canonical form (product of sums), then the transistor circuit output must be complemented, or the states 0 and 1 must be inverted.

2. If the complementary AND circuit, Fig. 1(D), is used exclusively, the diode and transistor configurations are similar only if the diode configuration ends in an AND gate, i.e., if the function has been factored in the second canonical form. If the function has been factored in the first canonical form, the transistor circuit output must be complemented, or the states 0 and 1 must be inverted.

3. The similarity between diode and transistor circuits holds only if every diode AND gate drives only OR gates, and vice versa, as is usually the case. If a diode AND (OR) gate drives another AND (OR) gate, then in the transistor circuit an inverter must be interposed between such gates.

E. J. McCluskey, Jr. (Princeton University, Princeton, N. J., and Bell Telephone Laboratories, Inc., Whippany, N. J.): Two interesting ideas are presented in this paper: first, the use of octal numbers for minimization of Boolean functions and, second, the formula for the saving in the number of diodes or transistors which is achieved by any given factoring operation. In connection with the minimization of Boolean functions, I should like to point out that use of a table such as that presented in my paper[1] eliminates the necessity of computing a list of the numbers of all terms which connect to the term being considered. Also, the use of Table III is unnecessary since the only computations required are additions of 1, 2, or 4 to a single digit of the number representing the term being studied.

In his discussion of minimal factored forms of Boolean functions, the author does not take into account the fact that it may be impossible to derive the minimal factored form directly from the minimal sum of products form. This is discussed in an article by William Burkhart,[2] in which one of the examples given is the function

$$F=(A+D)(B+CE)+DE'$$

T. J. Beatson: I should like to thank the discussers for their contributions. Mr. Lowenschuss' discussion shows that the detection of implicit functions must be included as part of any comprehensive minimization technique, and is a very useful addition to this paper.

My discussion of factoring states specifically that no method of obtaining minimal factored forms is known, other than the trial-and-error method. Usually there is some amount of insight associated with a trial-and-error procedure, so that if one tries long enough and hard enough he should be able to arrive at the particular factored form suggested by Mr. McCluskey.

Measurement of Voltage Resulting From Single-Phase Switching of a High-Voltage 3-Phase Transformer

W. F DUNKLE
FELLOW AIEE

W. F. MACKENZIE
MEMBER AIEE

SINGLE-PHASE SWITCHING of small high-voltage transformers with large turns ratios can result in excessive secondary voltages and damage to connected equipment unless these conditions are recognized and measures taken to mitigate these phenomena. Failure of switchgear connected to the low side of a 66,000/480 500-kva delta-delta transformer prompted investigation and measurement of voltages attained on two similar installations. Measurements were found to be in reasonable agreement with those determined analytically.

The problem is divided into two parts:

1. The first problem involves the steady-state 60-cycle voltage that appears across the secondary terminals. This voltage results from the secondary winding capacitance to ground being energized in series with the interwinding capacitance by the 39-kv-to-ground voltage of the system when one or two primary fuses are removed. The solution of this problem requires only a low-impedance circuit connecting the secondary delta to ground. Methods used for analyzing the problem were substantiated by the investigations.

2. The second problem involves high-frequency transient oscillations which occur when a primary fuse is being either removed or replaced, and pronounced arcing occurs to the fuse disconnect. It is believed that this phenomenon may also cause secondary flashovers.

Calculation of Capacitances

When the secondary of a small transformer is ungrounded, the secondary voltage under certain conditions may be calculated by using the relative impedances of the various winding capacitance and the primary voltage.

Data from periodic insulation power factor tests made in accordance with AIEE Publication No. 505[1] facilitated determining the winding capacitances of the transformer. This calculation was premised upon the winding reactances to ground being primarily capacitive.

Insulation Field Test Data

No. of test	Circuit	Test Kv	Ma*
1	High side energized, low side grounded	10	11.15
2	Low side energized, high side grounded	2	4.08
3	High and low side tied together	2	3.6

* Milliamperes. Referring milliamperes obtained on tests 2 and 3 to 10 kv, and writing the capacitive currents in terms of the component values obtains the following simultaneous equations:

$$I_H+I_{HL}=11.15 \quad (1)$$

$$I_L+I_{HL}=20.4 \quad (2)$$

$$I_H+I_L=18.0 \quad (3)$$

Subtracting equation 1 from equation 2, adding this result to equation 3, and solving the capacitive components when calculated, give the following values:

$$I_L=13.7 \text{ ma} \quad (4)$$

$$I_H=4.3 \text{ ma} \quad (5)$$

$$I_{HL}=6.7 \text{ ma} \quad (6)$$

Since the assumption was that all the impedance was capacitive reactance

$$E=I_z \times X_c$$

or

$$X_c=\frac{E}{I_z}$$

and using the values from equations 4, 5, and 6 for determining capacitance impedance values.

$$\text{Total } X_{c3}=X_{CL}=\frac{E}{I_L}=\frac{10,000}{0.0137}$$
$$=730,000 \text{ or } 0.73 \text{ megohm}$$

$$\text{Total } X_{CL}=X_{CH}=\frac{E}{I_H}=\frac{10,000}{0.0043}$$
$$=2,320,000 \text{ or } 2.3 \text{ megohms}$$

$$\text{Total } X_{C2}=X_{CHL}=\frac{E}{I_{HL}}=\frac{10,000}{0.0067}$$
$$=1,490,000 \text{ or } 1.49 \text{ megohms}$$

Calculation of Voltage

The calculations of phase-to-ground secondary voltages on the station service transformer at Hummelstown Substation were made, with the use of the high-side winding capacitance to ground, the interwinding capacitance, and the low-side winding capacitance to ground. They are shown schematically in Fig. 1.

To make these calculations, the assumptions were made that: 1. the winding capacitances were lumped together, 2 the capacitances were connected to the midpoint of the transformer windings, and 3 the winding capacitances were symmetrical and equal in value for each phase. Fig. 1 shows these assumptions diagrammatically. Voltage values calculated were for steady-state conditions only, and they may be considerably higher during transient conditions existing while the transformer primary is being switched.

The steady-state primary phase-to-ground voltages and also the primary mid-winding-to-ground voltages are shown in Fig. 2(A). The shape and size of the secondary delta is fixed by the winding ratio and cannot be changed. The secondary delta is centered around ground by assuming C_2 equal for each phase, and C_3 equal for each phase. Under normal operation the C_3-to-ground voltage would be 139 volts, while the C_2 voltage is 19.8 kv.

One Phase Switched Out

When one primary fuse is removed, Fig. 3, single-phase operation results, and the de-energized terminal assumes a voltage approximately midway between the energized phases. Since the voltages are fixed by the winding ratios, full voltage will be across one winding while half voltage will be across the other two windings. The voltages to ground of the secondary will depend on the relative magnitudes of C_2 and C_3. With 19.9 kv

Paper 58-35, recommended by the AIEE Special Instruments and Auxiliary Apparatus Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2-7, 1958. Manuscript submitted October 10, 1957; made available for printing November 4, 1957.

W. F. DUNKLE and W. F. MACKENZIE are with the Pennsylvania Power & Light Company, at Hazleton, Pa., and Allentown, Pa., respectively.

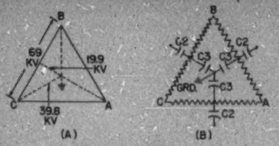

Fig. 2. Schematic representation of steady-state condition

A—Steady-state voltages to ground
B—Windings and capacitances

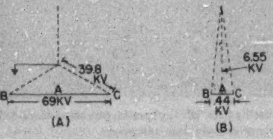

Fig. 3. Diagram showing voltages when one high-side fuse is removed

A—Primary
B—Secondary

across the capacitors C_2 and C_3, the secondary phase to ground voltage will be

$$V_{ABC} \text{ to ground} = \frac{0.73 \text{ megohms}}{2.22 \text{ megohms}} \times 19.9 \text{ kv} = 6.55 \text{ kv}$$

where 0.73 megohm is X_{C3} and 2.22 megohms is $X_{C3}+X_{C2}$

Two Phases Switched Out

In the case of Fig. 4, with two primary fuses removed, all terminals of the delta are at the same potential as the energized phase. This results in full 39-kv phase-to-ground voltage being impressed across C_2 and C_3 rather than the mid-winding voltage to ground as in the previous case. The secondary phase-to-ground voltage will therefore be

$$V_{ABC} \text{ to ground} = \frac{0.73}{2.22} \times 39.8 \text{ kv} = 13.1 \text{ kv}$$

Field Tests: Series 1

On December 14, 1954, tests were conducted on the 69,000/480-volt 500-kva station service transformer at Hummelstown Substation. The purpose of these tests was to simulate high-voltage conditions which had been experienced on switchgear connected to the 480-volt winding of this transformer and to obtain data for comparing calculated secondary phase-to-ground voltages against actual voltages obtained.

The tests were conducted under adverse weather conditions with rain falling continuously throughout the day. All measurements were taken at a switch box in the 66-kv yard with the secondary disconnect switch open. A 20-megohm resistance voltage divider was used to obtain voltage readings with a Triplett multimeter connected to a 2-megohm tap and ground. Test conditions were set up by removing and replacing primary fuses from the transformer with a switch stick as used under normal operating conditions.

On the first series of tests, voltages of 380, 100, and 340 volts, phase-to-ground, were obtained on the open secondary phases with C-phase primary fuse removed. These voltages are for A, B and C phases respectively. With B- and C-phase primary fuses removed, voltages of 600, 360, and 360 volts, phase-to-ground, were obtained on the open secondary phases. Fig. 5 showing connection of instruments. Preliminary calculations showed that these voltages should have been about 6 kv and 13 kv for the two setups respectively. Visual investigation as to the cause of the low-measured voltages as compared to the calculated voltages led to the conclusion that the asbestos base-fiber panel of the switch mount had absorbed moisture under the damp conditions prevailing, and that sufficient was leaking through the panel to reduce the voltages to the values obtained.

All three primary fuses were then removed, and a solid ground was connected to C-phase secondary terminal on the transformer. When A-phase primary fuse was inserted in its holder, and B and C primary phases open, readings of 370, 0, and 0 volts, phase-to-ground, were obtained on the open secondary phases. When an attempt was made to put B-phase primary fuse into its holder with A-phase primary fuse already inserted, unusually long arcs were noticed from the free end of the fuse to the fuse holder, and a flashover was observed to have occurred in the switch box. Upon removal of the switch panel the B-phase contact mounting screw was found to have flashed over to the metal switch box which was at ground potential. The clearance at the point of flashover between the contact mounting screw and the switch box was approximately 3/8 inch with sealing wax insulation between the two metals. The flashover appeared along the fiber mounting panel between the sealing wax and the mounting panel.

To secure better insulations to ground, a 1/4-inch Micarta panel was attached to the back of the switch-mounting panel, and the switch was remounted in the switch box. The first series of tests with the ground removed from the secondary were repeated. With one phase energized, the voltage measured on all phases to ground was approximately 10,000 volts. With two phases energized, voltage measurements on all three phases to ground were approximately 5,000 volts. During these tests, corona formations were noticed on the switch contacts and also between the panel-mounting screws and the panel board. Because of the adverse weather conditions, tests were discontinued. It was believed that adequate information had been obtained to substantiate the preliminary calculations.

Field Tests: Series 2

On January 12, 1955, a second series of tests were conducted on a similar 69,000/480-volt 500-kva station service transformer at Hosensack Substation. The objective was to compare data on this transformer with results obtained on the transformer at Hummelstown Substation.

The test setup and measuring circuit were identical to those used at Hummelstown. A cathode-ray oscilloscope was connected to one of the secondary terminals through a resistance voltage divider. Both transformers were similar as to voltages and ratings but of different manufacture, and the transformer secondary switches were of different design.

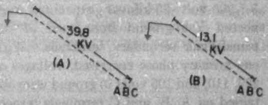

Fig. 4. Schematic representation showing voltages to ground with two high-side fuses removed

A—Primary
B—Secondary

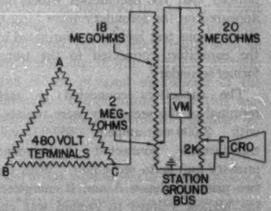

Fig. 5. Schematic of connections for measuring voltages to ground from transformer 480-volt terminals

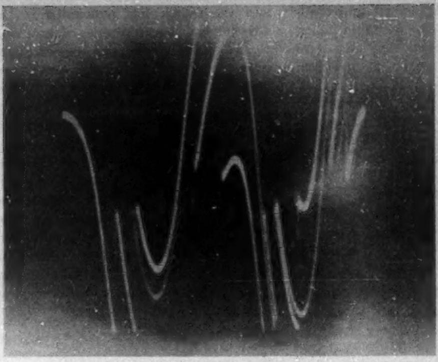

Fig. 6. Cathode-ray oscillogram of C-phase-to-ground voltage observed with A- and C-phase primary fuses removed

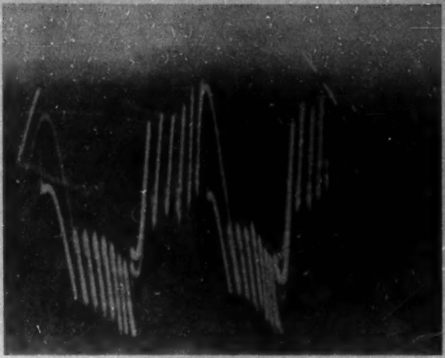

Fig. 7. Cathode-ray oscillogram of C-phase-to-ground voltage with C-phase primary fuse removed

With B primary phase energized and the secondary open, voltages of 750 volts to ground were measured on each phase. A considerable number of oscillations on the secondary wave form in the steady-state condition were noticed with this setup. A photograph of C-phase secondary voltage to ground was taken with the cathode-ray oscillograph, which is shown in Fig. 6. When A- and B-phase primaries were energized, voltages of less than 750 volts were obtained on each phase to ground. Fig. 7 shows this secondary voltage to ground on C phase.

These tests were then repeated with 3-7,200-volt 25-kilovar capacitors connected Y-to-ground from each of the transformer secondary terminals. With one primary phase energized, voltages of 220, 110, and 105 volts to ground were obtained on A, B, and C terminals respectively. With A- and B-phase primary phases energized, voltages of 145, 320, and 205 volts to ground were obtained. With all three primary phases energized, voltages of 260 volts to ground were obtained on all three secondary phases. It was noticed that the oscillations which had appeared on the secondary wave form in the previous test had been eliminated by the capacitors connected to the transformer secondary.

The capacitors connected to each terminal of the secondary were replaced with 3-500-volt-ampere 460/115-volt transformers connected Y-to-ground primary and delta secondary. With the two primary phases A and B energized, the highest voltage to ground was obtained on B phase, which was about 70 volts. With only B-phase primary energized, voltages of 87, 223, and 138 volts were obtained on A, B, and C secondary phases respectively. With all three primary phases energized, voltages of 260 volts to ground were obtained on all three phases. It was also noted that with this transformer type of grounding, the oscillations on the secondary wave shape were eliminated. With A-phase fuse in position and while the B-phase fuse was being put in its holder, B phase flashed over in the secondary switch mechanism.

Examination of the secondary switch disclosed that a Micarta insulating tube of approximately 1/32-inch thickness which fitted over a horizontal fastening bolt on B pole of the switch was missing, which reduced ground clearance at the point of flashover to about 0.125 inch.

Analysis of Field Test Results

As far as the 60-cycle voltages on the secondary are concerned, it appears that the connection of either transformer or capacitor to the secondary can hold the steady-state voltages to reasonable value. However, analysis of the condition under which flashovers occurred during switching indicate that the transformer is not adequate to reduce voltages during transients, but that capacitors are effective.

As a result of the tests, 2,000-volt oil-impregnated 10-microfarad capacitors were connected on both Hummelstown and Hosensack transformer secondaries. At each location capacitors were connected in Y between each phase of the transformer terminals and ground. The addition of these capacitors has entirely eliminated the high voltage resulting from single-phase switching.

From the tests the following preliminary conclusions were obtained:

1. An asbestos-base, fiber panel which is used to mount the secondary disconnect switch absorbs moisture, thereby reducing its electrical insulating properties.
2. Abnormally high voltages exist on the secondary terminals when single-phase switching is done under normal operating procedure.
3. The 60-cycle voltages which appear on the secondary during switching may be calculated from the interwinding capacitances.
4. The connection of the capacitors to the secondary minimizes the 60-cycle or transient voltage on the secondary during switching.
5. The connection of transformer to the secondary appears to minimize only the 60-cycle voltages on the secondary winding during switching.

◆

Discussion

S. Bennon (Westinghouse Electric Corporation, Sharon, Pa.): The authors have made a timely contribution by calling attention to the possibility of low-frequency overvoltages due to capacitance effects. The possibility of overvoltages for impulse waves has received considerable attention in the past, which might give the impression that the problem is associated only with lightning surges. However, as demonstrated by the authors, for certain types of excitation and for certain classes of transformers overvoltages can be produced at low frequency.

As the authors also indicate, voltage unbalance is necessary. Balanced 3-phase excitation applied to the primary of a 3-phase transformer with balanced winding capacitances will not displace the secondary. However, unbalanced excitation such as that produced by opening one or two lines will tend to cause winding displacement with respect to ground when the secondary is isolated.

These effects are most likely to be observed on transformers with low-voltage windings well below the 15-kv class. Above the 15-kv class the ratio of test voltage to operating voltage is set by the standards at a value of 2, but below the 15-kv class this ratio increases considerably. As a result, very low voltage windings, especially if they are overinsulated, will tend to have a lower capacitance to ground in proportion to their operating voltage than higher voltage windings. Thus, the percentage of the unbalanced voltage applied to the high voltage appearing between the low-voltage winding and ground will tend to increase. While these voltages will, in most cases, be within the insulation strength of the windings involved, they still introduce problems such as shock hazard and possible damage to associated equipment.

P. L. Bellaschi (Consulting Engineer, Portland, Oreg.): The paper exemplifies the importance that capacitance coupling between low- and high-voltage windings in transformers can have on the voltages developed in the low voltage. Under certain conditions, discussed in the paper, the voltage developed in the low-voltage winding can assume dangerously high levels sufficient to damage the insulation.

The high voltages developed in the low-voltage winding basically result from the high-capacitance coupling between the high- and low-voltage windings. Note that the ratio of the test levels for the two windings is not proportionately as high as the corresponding ratio of the capacitance coupling.

For instance, in the case cited, the electrical clearances from the 66,000-volt winding to the 480-volt would be in the order of one inch and from the 480-volt to the core or ground about 1/4 inch or less. Therefore, the induced voltage in the 480-volt winding is in the order of one fourth or thereabouts the voltage to ground of the high-voltage winding.

These overvoltages may be accentuated further as the result of switching operation. As pointed out in the paper, "capacitance loading" or various other loadings of the secondary will reduce the overvoltage to acceptable levels.

Difficulties of similar nature have been experienced in 3-phase transformers from impulse voltages induced into low-voltage tertiaries from high-voltage Y-connected windings. In some instances the cause of the failure could be ascribed to inadequate insulation or low insulation level and to floating tertiary. The paper amply illustrates how small things may develop consequential troubles.

J. B. Hodtum (Allis-Chalmers Manufacturing Company, Pittsburgh, Pa.): This extremely interesting paper brings up several ideas that may well prove to contribute to the voltage situation. For example, in a small unit the high-voltage bushing capacitance to ground may be such that when only one phase is excited, two phases of the winding can go into ferroresonance with the bushing capacitance. The question of ferroresonance, however, was not mentioned.

Recently, a considerable number of overvoltage troubles have been experienced on ungrounded delta systems, many of these on the 480-volt delta ones. Such systems have no fixed relation to ground except the inherent capacitance of the circuit itself. Should arcing ground occur on one phase, the other two phases result in an inductance-capacitance circuit due to the line capacitance to ground and the inductance of the circuit itself, and it may result in overvoltages. The installation of 25-kilovar capacitors on such a system may react as stabilizing means as long as arcing ground cannot occur on one phase of the circuit. Under arcing ground conditions the capacitors may exaggerate the voltage difficulties.

The use of potential transformers connected Y-delta with the Y point grounded acts as a limited grounding transformer. It therefore has the ability to fix the voltage to ground and prevent the accumulation of energy in the capacitance part of the circuit. However, should a fault occur on one of the legs of such a circuit, the potential transformer would be subjected to short circuit and would fail. It would be our recommendation that Y-delta grounding banks be used and that resistors be inserted in the neutral to limit the current to the rating of the grounding transformer bank. This current need only be enough to ensure that enough resistance is inserted in the inductance-capacitance circuit to prevent oscillation when arcing grounds occur.

W. F. Dunkle and W. F. Mackenzie: We are in full agreement with Mr. Bennon's statements and appreciate his substantiation of our thinking. Mr. Bellaschi's comments are also appreciated since they also confirm and substantiate our conclusions. We thank Mr. Hodtum for his comments and agree that the additional aspects of the problem which he mentions merit further investigation. However, utility funds and equipment to engage in this type of investigation are somewhat limited and this investigation was terminated when a practical solution to the problem was found. The use of Y-delta grounding transformers as a solution to this problem was found by test to be unsatisfactory, since this type of connection did not prevent a secondary flashover when arcing occurred on switching the second 66-kv phase. The reason for this secondary flashover was not explored.

Some Practical Mathematical Techniques

GORDON K. CARTER
MEMBER AIEE

THE various papers which have considered the subect of automation of engineering computations have shown that there are certain mathematical procedures, such as interpolation in tables and solution of equations, which occur with considerable frequency. In this paper an effort is made to give some more explicit information on a few of these procedures. It is not feasible to do more than indicate some of the methods which have been of value, but it is hoped that these may help to develop interest in a most fascinating and useful field. The way to further study is indicated by the references.

Although the discussion which follows is nominally separated into several discrete sections, there is considerable overlap of these topics both in theory and in practice. The reader is urged to approach them with the intention of understanding their principles, rather than of using them to classify any given computation in handbook fashion. Generally speaking, the successful application of numerical techniques is pretty much of an art, requiring understanding and patience; and the best method to use sometimes differs for apparently small differences between cases or problems. Mathematically, this may lead to long and elegant dissertations. But, from the practical standpoint, success often results from an understanding of the physical problem and of the physical significance of the associated computations. For this reason, it would be useful to visualize the

Curve Fitting

Exact Fitting of Tabulated Data

Tables of data are especially familiar in the form of function tables, such as sine or logarithm, and in the form of measured quantities, such as speed, current, or power. Among the most common operations on tabulated data are interpolation, integration, and differentiation. All such operations require something which the table itself is incapable of furnishing, namely, (1) the assurance that the table does in fact represent a (sufficiently) continuous function between the table entries, and (2) knowledge of how the function does in fact vary between the listed points. The table itself cannot give any information except what is in the table.

What reopens the door, thus unceremoniously slammed, is, of course, a knowledge of the function. It is known that the sine is a "smooth" function of the angle, or speed is a "smooth" function of the load. Of course, what is meant by a "smooth" function cannot be precisely explained but the meaning is clear. For instance, based on the data of Table I from a load test of a d-c shunt generator, the curve of Fig. 1 would appear to be a pretty good representation of this function. This is probably because a knowledge of the problem indicates that no humps are to be expected, and hence the points look close enough together to give good definition of the curve as drawn. Since the table did not show all this, though, it is clear that any automatic manipulations of the table must be made with due regard for the relationship of those manipulations to the function which they are supposed to approximate.

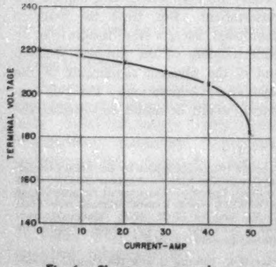

Fig. 1. Shunt-generator voltage

Linear interpolation is familiar to everyone. This is the equivalent of writing a linear equation, such as

$$V=a+bI \tag{1}$$

or

$$I=A+BV \tag{2}$$

to approximate the function. The coefficients are determined by causing the line to pass through the table points adjacent to the interpolated point; but, unless the equation of the line is particularly needed, this is not usually carried out explicitly, since it is shorter to interpolate by proportional parts. The linear function is the same whether it is as used in the form of equation 1 or of equation 2; and its relationship to the graph of the tabulated points is obvious, being the line segment joining the two adjacent points of the graph as in Fig. 2. These particular points have been chosen purposely, to show a rather poor approximation for the linear function.

If it is not possible, or convenient, to determine table values at a closer spacing, a closer approximation can be attempted by using higher degree polynomials, for instance, quadratic fitting:

$$V=a+bI+cI^2 \tag{3}$$

or

$$I=A+BV+CV^2 \tag{4}$$

The coefficients are determined by causing the quadratic to pass through the three points nearest the interpolated point. But now the two forms given in equations 3 and 4 are not usually equivalent, since equation 3 represents a parabola with vertical axis, and equation 4 one with horizontal axis. The only way to tell which is better is to see which agrees better with the smooth curve. This is generally true for nonlinear fitting. In the region shown in Fig. 2, for example, quadratic interpolation by equation 3 could be carried out by substituting the three corresponding sets of data into equation 3 and solving

$$\begin{cases} a+30b+900c=210.3 \\ a+40b+1{,}600c=204.7 \\ a+50b+2{,}500c=183.2 \end{cases}$$

This gives

$a=131.7$, $b=5.005$, $c=-0.0795$

and the result is shown in Fig. 3. The approximation is apparently better than linear over the right half of the region, but worse over the left half. The principal reason for this poor showing is the fact that the smooth curve is vertical, or nearly so, at 50 amperes; and polynomials of the type of equation 3 have difficulty in approximating this condition without producing bulges somewhere else.

Equation 4 could be fitted in the same way as equation 3, by solving suitable equations. Instead, it will be used as an example of the Lagrange method of writing the expression directly:

$$I=30\times\frac{V-204.7}{210.3-204.7}\times\frac{V-183.2}{210.3-183.2}+40\times\frac{V-210.3}{204.7-210.3}\times\frac{V-183.2}{204.7-183.2}+50\times\frac{V-210.3}{183.2-210.3}\times\frac{V-204.7}{183.2-204.7}$$

The form of this expression should be carefully noted, since it enables one to write a polynomial of any desired degree, through a corresponding set of points, with no more difficulty than shown here. Each term on the right consists of a value of the dependent variable (I), and a set of multiplying factors which take on the value 1 for the corresponding value of the independent variable (V) and the value 0 for each other value of the independent variable for the points used. This curve has not been plotted, but a few check points indicate that it gives a better fit than the straight lines in both halves of the range of Fig. 2.

This example has illustrated two ways of fitting a polynomial curve to given data points. The fitted curve, if it appears satisfactory, can then be used to estimate the value of the function between the table points (interpolation). Alternatively, the fitted curve can be integrated to give an estimate of the area under the function, or it can be differentiated to give an estimate of the derivative of the function. The validity of any of these operations cannot be assumed without suitable

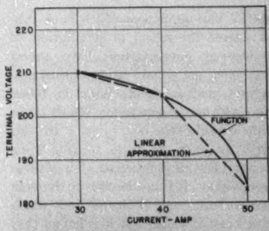

Fig. 2. Linear approximation

Vol.
Pt. 1
1958

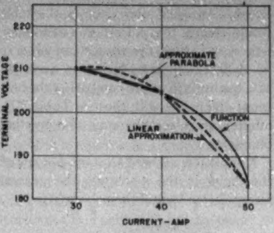

Fig. 3. Quadratic approximation

tests of the goodness of the fitted curve; however, it is generally the case that the integral tends to be better, and the derivative worse, than the quality evidenced by the fit of the function itself.

Because of the difficulty of checking fit, the exact fitting process is actually seldom applied to measured data. It is, however, extensively used for interpolation in function tables. It is also used in developing formulas for approximate differentiation and integration, especially for use in the numerical evaluation of integrals which cannot be formally integrated, and for use in the numerical solution of differential and integral equations which cannot be solved directly. Forms of other than polynomial type are normally avoided, unless there is a strong physical reason for introducing them.

APPROXIMATE FITTING OF TABULATED DATA

Especially for measured data, it is usually both appropriate and advisable to approximate the unknown function without attempting to fit the table points exactly. In this way it is frequently possible to obtain a suitably smooth approximating function which, at the same time, embodies the principal trends indicated by the tables. It is not too unusual in this case to make use of function forms other than the polynominal, such as exponential or sinusoidal forms, for example. This depends again upon knowledge of the physical situation, and it will not be pursued further here.

Whatever the form selected, the simplest case is that in which the dependent variable is assumed to be an explicit function of the indepedent variable. And the simplest treatment is to assume the values of the independent variable are true, while the values of the dependent variable are to be approximated. For example, consider the measured magnetic pull data of Table II, assuming the current values are correct. An attempt will be made to approximate the force using for the function

$$F=aI^2+bI^4 \qquad (5)$$

on the basis that the force should be zero for zero current, and that it should be an even function of current (same value for negative as for positive currents). Two conditions must be met. First, there must be more entries in the table than the number of unknown coefficients; this can be taken care of by using all four entries of the table to determine the two unknown coefficients. Second, there must be a reasonable criterion for good fit, one that makes sense and also provides a workable means of computing the unknown coefficients. Of those which are most often used, the best for many purposes is the least-squares criterion, used here for illustration.

Table II. Magnetic Pull Data

Current, Amperes	Force, Pounds	Force (Curve)
1	1	0.891
2	3	3.353
3	7	6.757
4	10	10.05

In view of the fact that equation 5 is not expected to be capable of fitting all the table points exactly, the error which it gives at each point of the table is noted:

$$\begin{cases} \epsilon_1=a+b-1 \\ \epsilon_2=4a+16b-3 \\ \epsilon_3=9a+81b-7 \\ \epsilon_4=16a+256b-10 \end{cases}$$

Under the least-squares criterion, the coefficients a,b are to be chosen such that the sum of the squares of all these errors is as small as possible

$$\Sigma\epsilon_i^2=(a+b-1)^2+(4a+16b-3)^2+ \\ \ldots+(16a+256b-10)^2=\text{minimum}$$

This is a polynomial (in fact, quadratic) function of a and b, and its minimum point will in general be such that the partial derivatives of the function with respect to a and b are zero; hence, with a factor of 2 removed,

$$\begin{cases} (a+b-1)+4(4a+16b-3) \\ \qquad +\ldots+16(16a+256b-10)=0 \\ (a+b-1)+16(4a+16b-3) \\ \qquad +\ldots+256(16a+256b-10)=0 \end{cases}$$

These equations suffice to determine a and b:

$$a=0.9081 \qquad b=-0.01748$$

The resulting curve has the values listed in Table II and the shape shown in Fig. 4, and would seem to be a sufficiently good representation for most manipulative purposes.

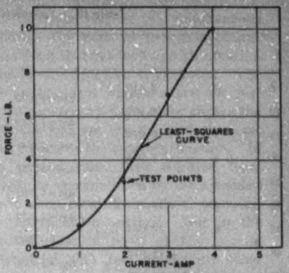

Fig. 4. Electromagnet pull test

The foregoing procedure, which is really quite simple in principle, is capable of application without much difficulty to almost any function form, so long as it is only the coefficients which need to be determined; thus, considerable latitude is available in the choice of function. If the number of table points just equals the number of coefficients, the result will be an exact fitting; but the labor will be greater than if the fitting is carried out in direct fashion.

The least-squares criterion is not necessarily the best for approximate fitting, although it is probably the simplest to use. The criterion that the sum of the absolute values of the errors be a minimum is sometimes preferred. Another useful one is that the magnitude of the largest error be as small as possible. In addition, it is possible to give the table values different weights, so that those which are considered most reliable have the most influence.

APPROXIMATE FITTING OF KNOWN FUNCTIONS

Surprising as it may seem, there is fairly frequent occasion to use an approximate representation of a function which is of known form. A familiar example would be the approximation of a rectified sine wave of voltage by means of a limited number of terms of its Fourier series. A less familiar, but very useful, case is the approximate representation of a segment of a sine function, say, by a finite polynomial expression so as to economize computing time with an automatic computer. Such approximations of known functions may permit the fitting criterion to be applied continuously over the whole interval, by integration, instead of by summation at discrete points as in the preceding section. The principles involved are just the same.

Table III. Calculation of Finite Differences

x	n	y				
5	0	2,119				
			$\Delta y_0=2,020$			
10	1	4,139		$\Delta^2 y_0=-89$		
			$\Delta y_1=1,931$		$\Delta^3 y_0=6$	
15	2	6,070		$\Delta^2 y_1=-83$		$\Delta^4 y_0=2$
			$\Delta y_2=1,848$		$\Delta^3 y_1=8$	
20	3	7,918		$\Delta^2 y_2=-75$		$\Delta^4 y_1=-3$
			$\Delta y_3=1,773$		$\Delta^3 y_2=5$	
25	4	9,691		$\Delta^2 y_3=-70$		$\Delta^4 y_2=1$
			$\Delta y_4=1,703$		$\Delta^3 y_3=6$	
30	5	11,394		$\Delta^2 y_4=-64$		$\Delta^4 y_3=-1$
			$\Delta y_5=1,639$		$\Delta^3 y_4=5$	
35	6	13,033		$\Delta^2 y_5=-59$		$\Delta^4 y_4=-2$
			$\Delta y_6=1,580$		$\Delta^3 y_5=3$	
40	7	14,613		$\Delta^2 y_6=-56$		
			$\Delta y_7=1,524$			
45	8	16,137				

It is interesting to find that the Fourier series approximation as usually described is, in fact, a least-squares fitting. The fact that the coefficients of the terms can be computed one by one, instead of by solving simultaneous equations as was done with the polynomial, is a result of the fact that the Fourier series components are orthogonal over the usual range of representation. This is an extremely valuable property for computation purposes since it permits direct observation of the improvement provided by each added term of the approximation.

A number of other families of orthogonal functions have found use in practical problems; e.g., the Chebycheff polynomials. The successive members of this family are polynomials of degree 0, 1, 2, and so on. They have the property that when a given function is approximated by a limited number of such terms, over the proper range, the maximum error of the approximation is the least that is possible by the use of a polynomial of that degree. For many purposes, as already mentioned, this kind of fitting is more advantageous than the more usual least-squares type.

Finite Differences

Another item to be considered under the general subject of curve fitting is the calculus of finite differences. In its most common (but not most general) form, this is a study of the properties of a polynomial which is fitted exactly to a set of data tabulated at equal intervals of the independent variable. These properties are explored in terms of the increments of the dependent variable, also called the "differences" of the function, whence the title. There is a very extensive literature on this topic. The general nature of it is a development in close analogy with that of differential calculus, with the differences corresponding to derivatives, summations to integrals, a general interpolation formula to Taylor's series, and difference equations to differential equations. Not only are the two systems formally similar in many ways, but also formal operational equivalences are developed which make it possible, for example, to write an expression for any specified derivative in terms of the differences, or conversely. As already mentioned, these matters are important in the development of approximate computing methods. They also turn out to be a useful means of studying the properties of certain types of systems of simultaneous equations arising from periodic structures or periodic switching phenomena.

While the subject cannot be studied extensively here, its nature can be indicated by exhibiting one form of the general interpolation formula, corresponding somewhat to Taylor's series in the calculus. The information in Table III starts with the independent variable x and dependent variable y, the former being taken at equally spaced locations.

The column headed "n" is a serial numbering of the x values to provide an equivalent variable with unit spacing; the location of the zero will be referred to later. The increments of y are written next to the spaces between y values and are designated here by one of several standard notations, Δ being read as "first forward difference of" the quantity following it. The subscripts correspond to the n's and would be changed if the location of the zero of n were shifted. The first differences constitute a tabular function also, and have increments or differences of their own. These are the "second forward differences of," denoted by Δ^2. And so on as far as desired. The fact that the actual numbers taper off and become substantially constant after a few differences is an indication that the tabulated function is closely representable by a low-degree polynomial in the range listed. An accidental error in the table would change this pattern in a characteristic way (which the reader can observe by deliberately introducing an error of, say, ten units in y_4 and comparing the new set of differences with those in Table III), offering an interesting way of correcting blunders.

Now, if n is allowed to stand for any of the digits in the n-column, the general interpolation formula may be written

$$y_n=y_0+n\Delta y_0+\frac{n(n-1)}{2!}\Delta^2 y_0+\frac{n(n-1)(n-2)}{3!}\Delta^3 y_0+\ldots \quad (6)$$

It is easy to verify, at least for the first few values of n, that this formula gives the numbers in the table. While not exactly the same as Taylor's series, it is clearly closely analogous in form, as already suggested.

A close look at Table III shows that Δy_0 depends only on y_0 and y_1; $\Delta^2 y_0$ only on y_0, y_1, and y_2; and so on. Thus if a definite number of terms is taken on the right side of equation 6, the formula involves exactly that number of terms from the table; and the formula will be found to give back only those same terms as values of n are inserted in it. So far, so good; nothing is obtained from the formula except the information that was put into it.

The next step is to observe that, if one now imagines n in equation 6 as a continuous variable, this expression becomes a polynomial in n of degree one less than the number of terms selected, and hence of degree one less than the number of points which it passes through. It is therefore *the* polynomial of lowest degree passing through the chosen points; and one has an alternative curve fitting scheme which is in many ways more convenient than either the substitution or the Lagrange method, although limited to evenly spaced points.

To be specific, from Table III,

$$y_n=2,119+2,020n$$

for the linear function through the first two points, or

$$y_n=2,119+2,020n-\frac{89}{2}n(n-1)$$

for the quadratic through the first three points, and so on. These functions can be used in all respects as before, for interpolation, for differentiation, for integration, or other desired purposes. The fact that they are expressed in terms of n has at least two features which need observation. First, best accuracy is provided by so placing the zero of n that the region of interest (interpolation point, derivative location, or region of integration) is centrally located with respect to the table points entering into the formula. Thus, to interpolate near $x=25$, using a second-degree formula, the zero of n is placed opposite $x=20$. Second, once the zero of n is located, it is a simple matter to determine the equivalence between x values and n values; this is required for describing the point at which interpolation or some other activity is to take place. The scale factor for differentiation or integration depends only on the x-spacing, since, for instance, from equation 6

$$\frac{dy_n}{dx}=\frac{dy_n}{dn}\frac{dn}{dx}=\frac{1}{\Delta x}\frac{dy_n}{dn} \qquad (7)$$

where Δx has the obvious interpretation.

In practice, the formulas developed by such methods as indicated are often translated back from the difference notation and given directly in terms of table entries. This frequently gives the best form for automatic computation; and it costs very little in the way of effort, since there are very simple relationships expressing differences in terms of table entries.

Solution of Nonlinear Equations

In engineering problems, solution of nonlinear equations or systems of nonlinear equations is a very common necessity. Frequently the need arises from trying to use interpolation formulas, or approximate fitted curves, in reverse. For instance, one might need to find the load current corresponding to a given terminal voltage from equation 3, or the current required to produce a given force in equation 5. A more complex case would arise, for instance, in trying to solve the heat balance relations for a turbine and its auxiliaries.

In the case of a simple interpolation function of one variable, as in the examples given here, one possibility is to set up the inverse interpolation function by simply interchanging the role of the variables. This would not, however, generally give the same results as the forward formula, as already noted. In simple cases the inverse of the forward interpolation function can be obtained though, and this is a desirable solution. Both equations 3 and 5, for instance, can be solved by the quadratic formula. Other simple solvable forms will occur to the reader, such as a single exponential or a simple trigonometric form.

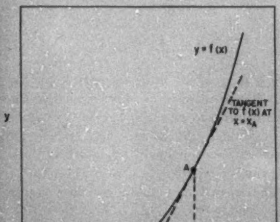

Fig. 5. Geometry of Newton's method

Aside from these simple equations, probably the greatest effort has gone into development of methods of solving higher degree polynomial equations. However, only two of the great variety of these will be mentioned. The first, which is equally applicable to other equation forms, is Newton's well-known method for real roots. It is assumed that the approximation x_A to the real root x_0 is known. The derivative of the function is evaluated at A, and the tangent to the function at A is projected to the x-axis, as in Fig. 5, to give the improved approximation x_B. The formal expression for this process is

$$\frac{y_A}{x_A-x_B}=\frac{dy_A}{dx}=f_A' \qquad (8)$$

or

$$x_B=x_A-\frac{f_A}{f_A'} \qquad (9)$$

The new approximation x_B can then be used in the same kind of expression to give a still better approximation x_C, etc. This process of using the result of a computation as the argument in a repetition of the very same computation is called iteration. Sometimes it leads to an answer (is convergent), and sometimes not. Newton's method is usually quite good in this respect, and inherently tends to converge rapidly. In most practical cases, the initial approximation can be reasonably rough, and may often be chosen on the basis of general knowledge of the physical situation.

It is worth while to realize, if the function cannot be differentiated, that Newton's method is only the limiting form of the method in which two nearby values of the function are calculated and the straight line joining these points used to find an estimate of the root. Both ways have their useful areas of application, and both can be used successfully when the function has more than one independent variable, or when several nonlinear functions of several variables must be solved simultaneously.

A particular case of two simultaneous nonlinear functions of two independent variables is that in which a given equation must be solved for its complex roots. The two independent variables are the real and the imaginary parts of the roots; the two functions are the real and the imaginary parts of the complex function. In the general case, their solution must usually be accomplished by the extended (2-variable) Newton's method, or multiple interpolation method. But in the case of complex roots of the general polynomial with real coefficients other ways have been developed, of which one is described as follows.

The basis of this method, which Aitken calls the "reduced penultimate remainder" method, is the determination of a quadratic factor of the complete polynomial expression. The polynomial with real coefficients has complex roots only in conjugate pairs, and each conjugate pair of complex roots can be expressed in the form of a quadratic factor with real coefficients; hence it is reasoned that the polynomial must have such quadratic factors in every case, and these are sought instead of the complex roots directly. Once a quadratic factor is determined, it may be solved by the quadratic formula. It is not universally agreed whether the real roots ought to be found and removed first, since the quadratic separation can equally well give pairs of real roots, too.

The method of reduced penultimate remainder is iterative, a first approximation to the quadratic factor being required. This approximate factor is divided into the polynomial by ordinary division or synthetic division, as preferred, the process being stopped before the last possible step of the division is performed. The remainder at this stage (the penultimate remainder) is also a quadratic expression, and is frequently a better approximation to a factor of the polynomial than the original trial divisor. It is therefore used as the next trial divisor, leading to an iterative process. As it leads to simplification of the arithmetic, the polynomial and the trial divisor are both written with leading coefficients of unity; accordingly, the penultimate remainder is "reduced" to that same form before becoming the new trial divisor. Thus the name, and this the process.

As an example, an attempt will be made to separate a quadratic factor of the equation

$$x^5+6x^4+11x^3+10x^2+6x+1=0$$

which is of the type met in the solution of linear control systems, except for the simple coefficients. There is no good rule for estimating a trial quadratic divisor, but one which works fairly often is to use the last three terms of the polynomial. Accordingly, the following factor will be tried:

$$x^2+0.6x+0.1$$

with results as follows:

$$\begin{array}{r|l}
 & x^3+5.4x^2+7.66x \\
\hline
x^2+0.6x+0.1 & x^5+6x^4+11x^3+10x^2+6x+1 \\
 & 1+0.6+0.1 \quad 0.54\ 0.77 \\
 & \qquad\quad 3.24 \quad 4.60 \\
\hline
 & \quad 5.4 \quad 7.66 \quad \mathit{4.86}\ \mathit{5.23} \quad \mathit{1}
\end{array}$$

The penultimate remainder is in italics. It gives for the next trial factor:

$$x^2+1.08x+0.21$$

It is easy to see how to continue the process. In the present case, it converges after four more trials to the factor

$$x^2+1.71x+0.35$$

and the quotient

$$x^3+4.29x^2+3.31x+2.84$$

each of which, equated to zero, gives possible solutions of the original equation. The quadratic is easily solved by the quadratic formula. It would probably be best in the case of the remaining cubic next to separate a real root; of course, this could have been done originally, as is sometimes recommended.

This method naturally does not always work so well as in the example given. Various modifications are available, with different convergence properties. Other completely different methods can also be used, including the 2-way Newton's method already suggested. These other methods involve more complicated procedures, but the Newton variety has the virtue of being applicable to nonpolynomial equations as well.

Simultaneous Linear Equations

In addition to appearing as the direct result of describing physical systems, as in the case of electric networks, simultaneous linear equations often arise in computation processes—as in curve fitting by substitution. They are also a result of the common practice of solving differential equations by means of finite difference approximation. This last source has two special features: It may lead to very large systems of equations, and, if the differential equation is nonlinear, the algebraic equations will also be nonlinear. Only two of the generally used methods of solving sets of simultaneous linear equations will be mentioned here but one of these, the iteration method, is applicable also to nonlinear systems.

SYSTEMATIC ELIMINATION OF VARIABLES

The method of solution by successive elimination of variables is the familiar process taught in high school and college. Several special circumstances arise when this process is utilized in automatic computation. The pattern of computation is usually fixed in order to make the procedure generally applicable; this sometimes leads to elimination in an unfavorable sequence or the occurrence of such difficulties as division by zero. The automatic process may not be able to recognize if the equations are not independent, and may supply wrong answers without warning of this condition. Where the number of equations is large, special arrangement of the computation may be required in order to avoid overloading the number storage capacity of the computer. To take care of such situations, many variations of the elimination method have been proposed.

The basic features are illustrated here by means of the following three equations:

$$\begin{cases} 8x+2y-3z=2 \\ 4x+10y+2z=3 \\ 2x-5y-9z=5 \end{cases}$$

In an automatic process, the first of these might be divided by 8, four times the resulting expression subtracted from the second equation, and twice the expression subtracted from the third, giving

$$\begin{cases} x+\frac{1}{4}y-\frac{3}{8}z=\frac{1}{4} \\ 0+9y+\frac{7}{2}z=2 \\ 0-\frac{11}{2}y-\frac{33}{4}z=\frac{9}{2} \end{cases}$$

The second of these expressions can now be divided by 9, one fourth of the result subtracted from the first equation, and 11 halves of it added to the third:

$$\begin{cases} x+0-\frac{17}{36}z=\frac{7}{36} \\ 0+y+\frac{7}{18}z=\frac{2}{9} \\ 0+0-\frac{55}{9}z=\frac{103}{18} \end{cases}$$

Finally, the third of these expressions is divided by $(-55/9)$ and the result used to eliminate z in the first two, in similar fashion:

$$\begin{cases} x+0+0=\frac{109}{440} \\ 0+y+0=\frac{129}{220} \\ 0+0+z=-\frac{103}{110} \end{cases}$$

Now, it is not claimed that this is the best possible way to solve equations, but it shows an interesting situation. All the steps of the solution were dictated by the left sides (coefficients) of the equations, whereas all the answers came from the right sides (constants). If these equations had to be re-solved several times with different sets of constants, all that would be necessary would be to remember the steps and apply them to each new set of constants to get the corresponding new set of answers. While this is possible, it is often more convenient to use a special way of "remembering" the necessary calculations, which will be illustrated by means of the same set of equations as before. Now, however, symbols will be used for the constants:

$$\begin{cases} 8x+2y-3z=a+0+0 \\ 4x+10y+2z=0+b+0 \\ 2x-5y-9z=0+0+c \end{cases}$$

The constant terms here have been purposely written in the same form as the variables came out in the previous answers. The steps now are exactly the same as before, and it will be observed that the constants a, b, and c remain in their original columns:

$$\begin{cases} x+\frac{1}{4}y-\frac{3}{8}z=\frac{1}{8}a+0+0 \\ 0+9y+\frac{7}{2}z=-\frac{1}{2}a+b+0 \\ 0-\frac{11}{2}y-\frac{33}{4}z=-\frac{1}{4}a+0+c \end{cases}$$

$$\begin{cases} x+0-\frac{17}{36}z=\frac{5}{36}a-\frac{1}{36}b+0 \\ 0+y+\frac{7}{18}z=-\frac{1}{18}a+\frac{1}{9}b+0 \\ 0+0-\frac{55}{9}z=-\frac{5}{9}a+\frac{11}{18}b+c \end{cases}$$

$$\begin{cases} x+0+0=\frac{2}{11}a-\frac{3}{40}b-\frac{17}{220}c \\ 0+y+0=-\frac{1}{11}a+\frac{3}{20}b+\frac{7}{110}c \\ 0+0+z=\frac{1}{11}a-\frac{1}{10}b-\frac{9}{55}c \end{cases}$$

The final set of expressions here can be used to compute in simple fashion the answers for any assumed set of constants; they constitute, in fact, the inverse, or general solution, of the original equations. It can be seen that they recall the steps of solution, not individually, but in a simple consolidated form. It is also clear that the work involved in obtaining this result is less than twice that of obtaining the original single solution. Cursory examination of the process indicates that in this presentation many quantities have been included unnecessarily. In automatic computation the letter symbols would not be stored explicitly, and there would be no point in storing the zeros, so each stage of the foregoing process would contain not 18, but only 9, numbers.

ITERATIVE SOLUTION

As with the elimination method, there are also many variations of the iterative type of solution. For simplicity, only one, generally known as the Gauss iteration, is discussed herein. The system of equations is examined and each of them associated with the variable which seems to be most strongly determined by it, a different variable with each equation. Each expression is then rearranged so that its associated variable stands alone on the left side. In the example, the most logical procedure is to use the variable with the largest coefficient as the associated variable, giving

$$\begin{cases} x=\frac{1}{8}\,(2-2y+3z) \\ y=\frac{1}{10}\,(3-4x-2z) \\ z=\frac{1}{9}\,(-5+2x-5y) \end{cases}$$

Assuming some initial estimate of the variables (often zero), these values are put into the right sides and new values computed. The new values then go into the right sides, and so on. The results of this process for several stages are as follows (the last column gives the true values):

$$\begin{cases} x: & 0.25 & -0.035 & -0.079 & -0.14 \\ y: & 0.30 & 0.31 & 0.45 & 0.48 \\ z: & -0.56 & -0.67 & -0.74 & -0.82 \end{cases}$$

$$\begin{array}{rrrr} -0.18 & -0.20 & \ldots & -0.25 \\ 0.52 & 0.54 & \ldots & 0.59 \\ -0.85 & -0.88 & \ldots & -0.94 \end{array}$$

That the process is not unique can be seen by the fact that another arrangement of the same equations is

$$\begin{cases} x=\frac{1}{10}(2+2x-2y+3z) \\ y=\frac{1}{10}\,(3-4x-2z) \\ z=\frac{1}{10}\,(-5+2x-5y+z) \end{cases}$$

Since the iterative process is a nonterminating one, which in some cases may not even converge, while the elimination method gives a theoretically accurate answer with a definite number of operations, the advantage of iteration is not too evident. It is, however, very handy for the type of equations encountered in the numerical solution of differential equations; these may be large sets of equations, each of which contains only a few of the variables. In hand computation, iteration has the additional advantage of automatically correcting any errors, and hence of permitting initial work to proceed with fewer figures than might ultimately be required. And, as already mentioned the principle is equally applicable to nonlinear systems.

LATENT ROOTS AND MODES

In a large class of problems one has to consider systems of homogeneous linear equations containing an unknown parameter in the coefficients of the variables. Such systems occur in the study of transients in electric networks or in feedback control systems, the parameter being the (complex) system frequency. In these cases, it is sometimes necessary to determine the frequencies (latent roots) which permit the equations to have nonzero solutions and, in addition, the nature of these solutions (modes). Such calculations fall under the general heading of linear equations, although some procedures require the frequencies to be found from solution of a polynomial or other nonlinear equation. The objectives of this paper permit no further treatment of this type of problem.

Matrix Algebra

The subject of linear equations can hardly be dismissed without mention of matrix algebra. The principles involved in the parts of this topic which are of primary interest in engineering computations are relatively easy to understand, and they are almost indispensable in trying to follow the many ingenious and fascinating methods which have been proposed. On the surface, the nature of matrix algebra is the definition and use of an operational notation which allows the description of a set of simultaneous equations in the form of three symbols: one for the set of coefficients of the variables, one for the set of variables themselves, and one for the set of constants. Because of the algebraic properties of these symbols, it is possible to use them in devising many procedures, both finite and iterative, which would be difficult or practically impossible to discover from the detailed equations.

Differential Equations

It has already been pointed out that a very popular way of obtaining solutions to differential equations at the present time is by making use of finite difference approximations to convert them into corresponding simultaneous algebraic equations. The latter are then solved by the methods which have been indicated, or similar methods; and it is hoped that the resulting solutions form an adequate estimate of the true solution of the differential equations—or, even better, of the physical problems. Such a happy result cannot be taken for granted, though, so there is still great opportunity for the exercise of good judgment and ingenuity in this process.

In this particular field it is worth emphasizing also that such methods are only a supplement to, and not a replacement of, the other available methods. For example, there are classical, closed-form solutions, which give compactly the influence of the parameters of the equations; variational (such as Rayleigh-Ritz) solutions, which permit successive improvements and sometimes error estimates, as well as giving good matching of the boundary conditions; and analog solutions, which are sometimes faster than numerical integration methods and sufficiently accurate for many engineering problems.

Error Analysis

The use of numerical methods leads inevitably to the question of accuracy of the results. This refers not only to the effects of errors or uncertainty of input data and of the mathematical formulation of the physical problem, which would affect the results of any type of analysis, but also to those errors which are inherent in the numerical processes. Aside from arithmetic errors, or blunders, which an effort is made to eliminate by suitable checks and tests, two important types of error are easily recognized. One of these is called truncation error. This is the type of error introduced by retaining only a finite number of terms of a series approximation (curve fitting); or by using finite increments to approximate derivatives and integrals (differential equations, which is still curve fitting); or by using an iterative process, which must necessarily be terminated after a finite number of repetitions. The other is called round-off error, which is probably self-explanatory; it comes from the necessity of retaining only a finite number of digits in any arithmetical calculation.

Much effort has gone into studies of these matters. Generally usable results are relatively scarce and usually difficult or impractical to apply. Good engineering judgment often offers the most useful means of estimating reliability. Which brings this paper right back to where it started, to the suggestion that numerical methods are often as much of an art as a science; that they are a fascinating study and a continual challenge.

Information Sources

The literature in the field of numerical methods is very extensive, both in the form of books and as articles in periodicals. The variety is also great, ranging from direct applications to specific problems, to abstract and difficult mathematical treatments. The following lists those books which have been found useful and most understandable from an engineering point of view; the list is not exhaustive, and it contains much duplication. Any of the books named offers a good entry into the field of numerical methods and leads directly, through its references, into the pertinent current literature.

Electric Hygrometer

W. H. MEIKLEJOHN
MEMBER AIEE

AN ELECTRIC HYGROMETER is a device used to measure relative humidity (RH) by electrical means. Mechanical methods are exemplified by the hair hygrometer and the sling psychrometer. An electric hygrometer was developed by Dunmore[1] and used extensively in radiosondes to obtain upper-air data for the United States Meteorological Service. The electric hygrometer described in this report has a lower resistance than the Dunmore hygrometer. The lower resistance of this hygrometer allows direct operation of relays with the hygrometer current.

Operation

A schematic diagram of the electric hygrometer is shown in Fig. 1. The resistance of the hygrometer varies with the RH or water vapor pressure in the air. The pores of the glass contain a salt solution in the form of a film on the surface of the pore which absorbs more water when an increase in RH occurs. The resistance of the solution in the pore decreases and more current flows. Similarly, a decrease in current is obtained with a decrease in the RH.

Electrolytic conduction takes place between the porous metal electrodes. If the salt used has a decomposition potential lower than water, the salt will plate out, and the hygrometer will fail, because of loss of salt. Therefore a salt such as lithium chloride which has a decomposition potential higher than water is used, so that hydrogen and oxygen are plated out at each electrode. If these gases are allowed to accumulate the hygrometer will fail, because of the loss of water in the pores. To eliminate this difficulty, alternating current was used to cause recombination of the hydrogen and oxygen to form water.

Construction

The porous glass used in the hygrometer was obtained from the Corning Glass Works in the form of square sheets 2 inches on a side and in both 0.005- and 0.010-inch thicknesses; see Fig. 2. The porous glass occurs in a stage of the process of making Vycor brand 96% silica glasses, sometimes called reconstructed glasses. A soft alkali borosilicate glass containing many alkali compounds is molded into the desired shape, and then all the alkali compounds are leached out, leaving behind a porous network of silica with some of the leaching salts still in the pores. It is at this stage that the glass is used for the electric hygrometer.

The glass for the hygrometer was

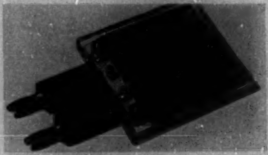

Fig. 3. Assembled hygrometer

treated to remove the leaching salts left in the glass during the leaching operation, and a 0.1 normal lithium chloride solution was introduced. The glass was placed in a breaker of distilled water for 3 days. The water was changed twice each day. The glass was then placed in a 0.1 normal solution of lithium chloride for 3 days. The solution was changed each day. Attempts to force the solution through the porous glass resulted in broken glass plates, even when the porous glass was backed with fritted glass which had been ground flat.

The surface of the porous glass was cleaned of salt by dipping the glass in distilled water several times. The porous glass was not allowed to stay in the distilled water long enough to change materially the concentration of lithium chloride in the pores.

The porous glass was placed in an evaporator and a 0.01μ (micron) film of gold and a 0.1μ strip of gold were evaporated on each side of the glass. The two strips were arranged perpendicularly to each other in order to reduce the area covered by such a thick film. The thick film would be less permeable to moisture and would cause an increase in response time of the instrument.

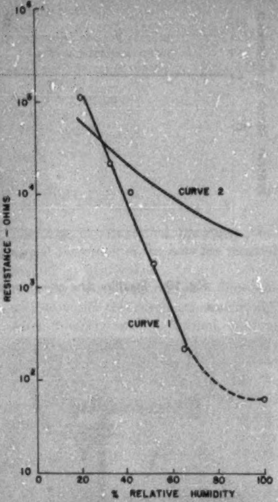

Fig. 4. Curve 1—Hygrometer resistance as function of RH. Curve 2—Calculated resistance variation

The porous glass was mounted between frames, as shown in Fig. 3. The glass was cemented to only one frame at only one spot. Copper wires of the proper diameter were used as spacers, so that the frame would not restrict the motion of the glass and cause cracking. The glass changes its dimensions considerably with changes in relative humidity as well as with temperature. Electrical contact was made to the evaporated gold strips by means of mechanical pressure.

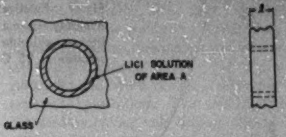

Fig. 5. One pore in reconstructed glass

Resistance

The variation of resistance of one hygrometer with RH is shown in curve 1, Fig. 4. The resistance change from zero to 100% RH is more than 4 decades. The resistance per square centimeter of porous glass surface in the humidity range of 20% to 65% is given by

$$R=8\times10^4e^{-0.188H} \quad (1)$$

where H = per cent of RH and R = ohms/cm² (per square centimeter). The resistance values are low enough to allow the hygrometer to be used in series with a relay to control some other device directly. The self-heat error in the hygrometer should be lower than the self-heat error of other electric hygrometers because of the lower resistance.

The expected resistance variation with RH may be calculated.[3] Consider one pore in the porous glass as shown in Fig. 5. The pore contains lithium chloride in solution of cross-sectional area A. The pore has a length L so that the resistance R is given by

$$R=\frac{L}{\sigma A} \quad (2)$$

where σ = conductivity mho/cm. There are the following relations:

$$\sigma=C\lambda \quad (3)$$

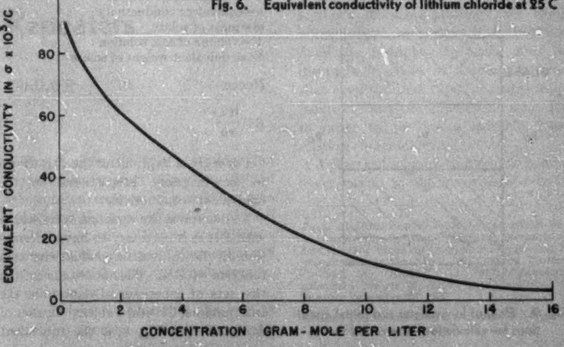

Fig. 6. Equivalent conductivity of lithium chloride at 25 C

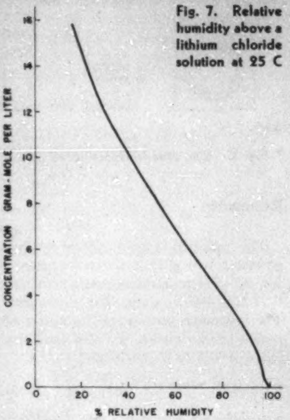

Fig. 7. Relative humidity above a lithium chloride solution at 25 C

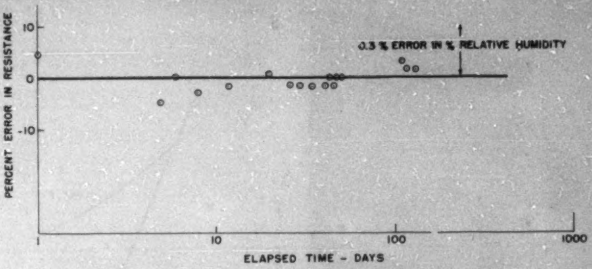

Fig. 10. Stability data on hygrometer having lithium chloride in its pores

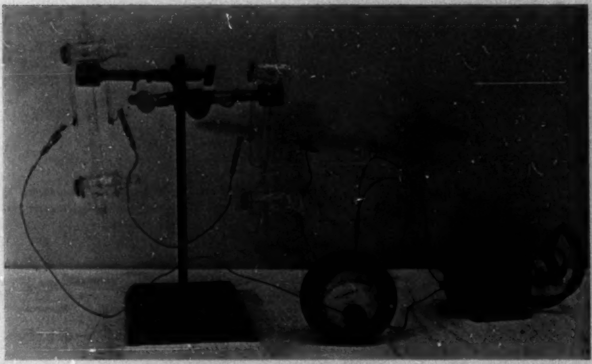

Fig. 11. Apparatus used to determine per-cent recombination of hydrogen and oxygen in pores of hygrometer

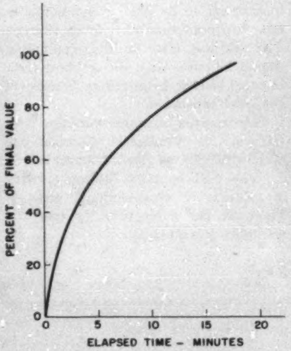

Fig. 8. Response time of reconstructed glass hygrometer

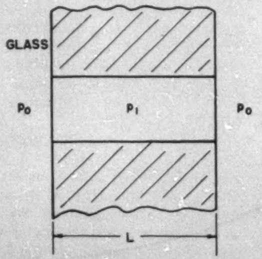

Fig. 9. Pore of hygrometer and initial conditions for calculation of response time

$$C=\frac{m}{VW} \tag{4}$$

where

C = concentration of salt
λ = equivalent conductivity
m = mass of solute
V = volume of salt solution
W = equivalent weight of solute

Hence

$$R=\frac{WL^2}{m\lambda} \tag{5}$$

For a given hygrometer the R is shown to be inversely proportional to the equivalent conductivity.

To determine the variation of resistance with RH it is necessary to have information on the equivalent conductivity as a function of RH. This is obtained from two sets of experimental data from the International Critical Tables. One set of data shown in Fig. 6, is the equivalent conductivity as a function of concentration. The other set, shown in Fig. 7, is the RH as a function of concentration. With these two sets of data and equation 5, the expected resistance variation has been calculated. The result is shown as curve 2 in Fig. 4. The agreement with experiment is only qualitative.

Response Time

The response time of the hygrometer to 63% of its final indication is about 7 minutes; see Fig. 8. The response time is long because the pores in the glass are so small. If the pores are made large enough (1μ) to be several times the mean free path of the water molecules in the air, then the response time should be less than one second. This has been verified experimentally, and some rough calculations will be given to show that a response time of one second should be expected.

The pores in the reconstructed glass are 40 to 60 Å (Angstrom units) in diameter and only 65% of the surface area is glass. If one assumes an equally spaced array of holes in the surface, then it is easily shown that the pore separation is about 70 A. However, the mean free path of water vapor molecules at standard temperature and pressure is about 600 A. It is difficult under these conditions for the water molecules to get into the pores, and correspondingly difficult for them to get out.

If the glass has a pore size of 10,000 A (1μ), then the water molecules can easily diffuse into and out of the pores. In particular, they will obey Fick's laws of diffusion.

Consider the 1-dimensional case of diffusion

$$\frac{\partial p}{\partial t}=D\frac{\partial^2 p}{\partial X^2} \tag{6}$$

where p = partial pressure of water vapor.

This equation may be solved for the case shown in Fig. 9, where the initial condition is that of the hygrometer, removed from a jar having a vapor pressure p_1, and into the atmosphere at pressure p_0. The solution of this equation is

$$p=p_0+\sum_{n=0}^{\infty}\frac{4}{\pi}\frac{(p_1-p_0)}{(2n+1)}e^{\frac{-(2n+1)^2\pi^2}{4L^2}dt}\cos\frac{(2n+1)\pi X}{2L} \tag{7}$$

The infinite series converges so rapidly that the first two terms are a very good approximation:

$$p=p_0+\frac{4}{\pi}(p_1-p_0)\cos\frac{\pi X}{2L}e^{\frac{-\pi^2 dt}{4L^2}} \tag{8}$$

Assume that

p_1 = 8 millimeters of mercury: 50% RH at 20 C (degrees centigrade)
p_0 = 3 millimeters of mercury: 20% RH at 20 C
D = 1/4 cm²/second
L = 0.1 cm
T = 0.01 second

then

$$\frac{p-p_0}{p_0}=0.14 \tag{9}$$

Therefore, in 0.01 second, the vapor pressure at the center of the pore has reached 86% of its final value.

An ultrafine (1μ) porous glass filter was used to verify this result experimentally. After filtering a 0.1 normal lithium chloride solution through the porous glass, the excess glass was cut off. Gold was evaporated on each side of the glass and the response time was measured to be less than one second. The resistance was very high because of the greater thickness and the reduced total circumference of the pores.

The response time of the hygrometer can be greatly reduced by using porous glass with pore diameter in the range of 0.1 to 1μ.

Stability

Stability data on a hygrometer tested in a closed container above a salt solution at 52% RH and at a constant temperature of 25 C are shown in Fig. 10. Because of the high sensitivity of the hygrometer a 10% error in resistance at 52% RH results in only a 0.3% error in the indicated RH as shown in Fig. 10.

The principles involved in making this hygrometer stable are very simple. Since electrolytic conduction takes place in the hygrometer, there must not be any metallic ions present to plate out on the electrodes and hence change the conductivity of the solution. This condition is obtained by having only lithium chloride salt in the pores of the hygrometer. Since lithium chloride has a decomposition potential higher than water, hydrogen and oxygen are plated out at the electrodes. The gas formation at the electrodes would also result in instability, and therefore it is necessary to cause recombination of the gas. Hence, the hygrometer must be used on alternating current in order to have both oxygen and hydrogen available for recombination. If the frequency of the alternating current is high enough, the oxygen and hydrogen will recombine. The test shown in Fig. 11 was devised to determine whether 60 cycles per second is a high enough frequency.

The test consists of electrolyzing a 0.1 normal lithium chloride solution and collecting the gas. There was no gas formation observed. Assuming that the gas bubble to be detectable would have to be at least 0.1 cm in diameter, and that the liquid would first become saturated with the gas, one may calculate that the efficiency of recombination is at least 99.999%. It may be concluded that in a pure water vapor atmosphere this hygrometer should be very stable.

Transistorized Negative-Impedance Telephone Repeaters

ROBERT P. DIMMER
NONMEMBER AIEE

PRESENT switching plans which utilize automatic switching equipment in the telephone plant call for many changes in the layout of circuits and routing of traffic. Where yesterday traffic was handled in as direct a path as possible with a minimum of switching, today one or more different routings may be used to connect the same two telephones at different times.

The inception of this switching plan immediately presents a problem to the transmission engineer, for it is he who must keep the transmission loss of each individual circuit as low as possible in a connection in order that transmission will always be satisfactory on all calls irrespective of routing.

One might consider that the way to solve this problem would be to operate all circuits at zero or close to that loss, and thus make the transmission independent of routing. A study of the methods of accomplishing this would immediately show that it is not economically possible. In some cases the distances involved in a circuit indicate that even the best types of transmission facilities must be operated at some loss in order to provide a suitable transmission characteristic.

A practical solution would be to operate every circuit at the lowest loss possible

considering its length and the type of facilities used. It would also be desirable to maintain these circuit losses within narrow limits because losses, either positive or negative, can accumulate on a connection with many links and produce either too low a speech level or excessive echo or hollowness.

One way to minimize the losses on 2-wire voice circuits would be to provide some type of voice amplifier or repeater to such circuits. In this case, would be necessary to treat each link of a connection in the same fashion, because a call might be routed through many different combinations of circuits at different times. In a typical telephone exchange there are many thousands of such circuits which might be used at one time or another to make the connections. Therefore, if this technique is to prove satisfactory, the voice repeater used should be one of small size and low power consumption, require practically no maintenance, and be low in initial cost. These features eliminate the hybrid type of repeater because of its size and cost, and suggest the negative-impedance type.

The negative-impedance type of repeater has been in use for some years and has proved its worth in many such applications. Unlike the hybrid-type repeater, this new repeater is essentially a device which, instead of amplifying in the usual sense of the word, in effect places a negative impedance in series with the line. The effect obtained with this repeater is to cancel an equal positive impedance naturally inherent in the line, and raise the transmission level accordingly. The shunt-type repeater was introduced some time after the negative-impedance type and eliminated some of the undesirable effects caused by the series unit. With both repeaters working as a team, the transmission engineer finally has a tool with which he can reduce the loss on multiswitched connections at a cost within reason.

The first negative-impedance repeaters employed vacuum tubes, but a forward step was taken when the newly developed transistor was considered for use in this unit. Transistors exhibit none of the practical limitations of the vacuum tube such as bulkiness, requirements of a heated filament, relatively short life, gradual deterioration with age, high anode voltage, or limited ruggedness. On the other hand, they do possess such desirable characteristics as small size, low power consumption, low voltage requirements, and apparent unlimited life. This paper will deal with a transistorized version of the negative-impedance-type repeater; specifically, the series-type *AT-2* and the shunt-type *AT-3* manufactured by the Automatic Electric Company.

Description

The series-type *AT-2* repeater is shown in Fig. 1. Its mate, the shunt-type *AT-3*, is identical in outward appearance. An inside view of the shunt unit is shown in Fig. 2 with an arrow pointing to the transistors. These transistors are mounted between two aluminum plates which act both as a mounting device as well as cooling fins to keep the transistors in a stable operating condition. A shelf of eight repeaters is shown in Fig. 3.

Either unit measures approximately 2 inches in width and $9^1/_4$ inches in over-all depth and a shelf of repeaters occupies a height of $5^1/_4$ inches. Eight repeaters will fill a single shelf designed to be mounted on a standard 19-inch relay rack, or ten units can be mounted on a 23-inch rack. Each repeater slides on a track to engage an 8-point shelf jack which is adjusted at the factory to cause the lines on both sides of the repeater to become connected when a repeater is removed. This feature permits rapid replacement of a defective unit if trouble should occur without interrupting an existing conversation.

Either repeater uses two conventional type-*2N44* alloy junction p-n-p transistors operating in a type of push-pull circuit. The adjustable part of either unit contains a number of graded values of resistance, capacitance, and inductance which may be combined by strapping in the field to give the desired network configuration and values in order that the repeater

may be made adaptable to practically all exchange facilities. Access to the terminals connected to these components is provided by removing the top cover of either unit.

Strapping tables are furnished to enable the user to install these repeaters quickly on the most common types of cable. Where a mixture of cable is encountered, an installer's set is available which permits the rapid selection of network component values to satisfy the particular line condition. The values determined by this method would then be duplicated in the repeater strapping panel.

Operation

The negative-impedance-repeater concept has been covered by previous authors[1–5] on circuits using vacuum tubes; some few have considered the transistor approach. This type of repeater is different from the usual hybrid coil repeater, very familiar to transmission engineers, in that it uses only one amplifier and one network for a complete 2-way 2-wire voice repeater. The network in the new repeater performs the function of gain adjusting rather than balancing. By changing the constants in the network one can change the gain equally over the voice-frequency range, or if desired, the gain can be changed differently at various points within the band, thereby providing a means of equalization. No external filters or equalizers are required, and no additional signaling bypass equipment is needed. Direct current for talking battery and supervision and the various signaling voltages usually encountered in the telephone exchange pass through the repeater with very little difficulty. This type of repeater has the added advantage that, in the event of failure of some component within the unit, the circuit will still function but with its loss raised until the defective unit has been replaced.

The basic circuit of the transistorized series-type *AT-2* is shown in Fig. 4, and of the shunt-type *AT-3* is shown in Fig. 5. The repeaters are connected to a line by the method shown in Fig. 6. In this case the combination repeater would be called the *AT-23*. Either repeater consists of three principal parts: (1) coupling device; (2) balanced transistor amplifier or converter stage; and (3) network.

The series repeater is coupled into the line by a conventional transformer with a 1-to-1 ratio so connected as to insert equal amounts of negative impedance in series with each side of the line, to maintain line balance. This ratio was chosen to prevent high secondary transients from damaging the transistors. In the shunt repeater, the converter is coupled across the line through a resistance-capacitance network. The resistance provides the proper repeater gain, and

the capacitors serve as isolation for any type of d-c signaling or dialing on the telephone circuit. It can be seen that the shunt repeater circuit is basically the series circuit in reverse; in this case the collectors of the transistors serve both as input and output terminals of the device, and the gain-adjusting network is connected to the emitters.

To analyze the operation of the circuit in Fig. 4, assume that two subscribers are engaged in a conversation on a particular telephone circuit which contains a series-type transistorized negative-impedance repeater similar to that shown in Fig. 4. Their voice signal is coupled to the emitters of the transistors in a push-pull fashion. Because of the characteristics of p-n-p junction transistors with an alpha value close to 1.0, practically all the emitter current going into either transistor flows out of its own collector into the load, developing a voltage across it. This voltage is cross-coupled back to the bases of the opposite transistor, and thence to the input terminals practically undiminished because of the low impedance of the operating transistor between emitter and base. Therefore, the voltage back to the input is practically the negative of the voltage across the load, and one can see at the input the negative of the load impedance. The base voltages appear at the emitters because the transistors behave essentially like cathode followers. Since the current entered the emitter of the first transistor and left via the emitter of the opposite transistor and conversely, the repeater might be considered a generator. With the transistors used, the collector current is only slightly less than the emitter current, and the emitter-to-base resistance is under 100 ohms; hence this analysis seems quite correct.

As is the case with all repeaters of the series type, the device is short-circuit unstable. In terminal repeater applications, the series repeater will oscillate if a short circuit is encountered on the line side during a dialing condition. The shunt repeater has the opposite characteristic, that is, it is open-circuit unstable. If the line should become open-circuited on the side near the repeater, the unit will oscillate during an idle circuit condition, assuming that no idle circuit termination is used. Generally speaking, a dialing condition for the series repeater and an open-idle-circuit condition for the shunt repeater are the controlling factors governing the amount of gain possible. Oscillation which occurs due to these conditions will be the limiting factor. In a terminal repeater, crosstalk limits are also controlling.

The use of transistors allows the use of an input transformer with smaller resistance windings; consequently, the line would show less loss if a repeater should fail. In the voice-frequency range, the *AT-2* adds about 6.0 db (decibels) of loss during this failure, and the *AT-3* about 1.0 db. With these orders of losses it is still possible to maintain reasonably good levels if the speaker raises his speaking level.

The conversion ratio in these units is determined by the value of the cross-coupling resistors *R14* and *R15* on the *AT-2*, and *R5* and *R6* on the *AT-3*. Any required ratio can be obtained by simply changing their values. The conversion ratio of the *AT-2* using 15,000-ohm resistors at these points is approximately 9 to 1. For example, if a 9,000-ohm resistor is used as the network, the negative impedance in series with the line would equal approximately 1,000 ohms. This ratio is also effected by the values of *R6* and *R7* across the converter side of the input transformer. These resistors were used to permit the use of a conventional 1-to-1 telephone-type repeat coil as input transformer.

Both repeaters were designed to operate from a single 48-volt battery source, typical in most automatic telephone exchanges. At this voltage each repeater draws about 20 milliamperes of current, or about 1.0 watt of power. As heat radiation is not a controlling factor at this low value of power consumption, fans or additional cooling devices are not required. To obtain the opposite bias voltages required by transistors, their bases are connected to the center tap of a voltage divider. This connection makes half the source available for the emitter and half for the collector of opposite polarity. Each emitter circuit has individual dropping resistors to set their operating point. This method has proved more satisfactory when transistors with wide variations are encountered. It also permits the control of repeater gain below 500 cycles by changing the value of *C1*. This limitation offers some desirable features such as greater gain in the voice band, a certain degree of noise suppression, and the reduction of the series repeater's effect on various signaling voltages. It also affords a control of the low-frequency oscillation which this repeater originally developed on nonloaded telephone circuits.

The conversion property or alpha of a transistor varies little with bias conditions, and consequently a change in supply voltage should have little effect on the insertion gain of a series repeater within certain limits. Fig. 7 shows the change that occurs in the gain of this unit when the supply voltage is changed from 0 to 50 volts. Note that the gain remains practically constant from 20 to 50 volts. This feature permits the pole-mounting of repeaters and supplying them with power from a distant office by using a spare pair in the cable. It might be possible, in some cases to supply each repeater over its own line pair, but each installation would have to be engineered differently in view of the many types of signaling and dialing one encounters in telephone systems. The drop in supply voltage affects only the output capabilities of a series repeater. As this voltage drops as it is extended farther and farther from the office, so also does the input signal; consequently, one would still have a satisfactory repeater. The gain of the shunt repeater drops in proportion to the supply voltage with a constant network. The gain of this unit however, can be returned to the standard value as obtained with a 48-volt supply by using a higher gain network. This unit does not have any output capabilities limit within the range of levels encountered. With a 24-volt supply source, and with proper selection of the *AT-3* network, it is possible to realize full output with the combination *AT-23* as a mid-point repeater. In this application each repeater would draw only 10 milliamperes of current and thus the pair would consume only 0.5 watt.

The *AT-2* repeater with a supply voltage source of 48 volts will handle outputs up to approximately 10 volume units before distortion is perceptible, and the *AT-23* combination will handle slightly higher outputs.

The repeaters have remained undamaged up to a temperature near 100 C (degrees centigrade) although at this high temperature other components within the units did become damaged. The gain of the unit remained constant up to about 60 C, as shown in Fig. 8. Beyond this temperature the gain dropped until it reached zero at about 90 C. Compensation was considered, but temperatures in telephone exchanges rarely reach these values. For pole-mounted repeaters a fan should be used when temperatures above 60 C are reached. If these high temperatures are reached at any time, the transistor invariably returns to normal when the temperature is reduced to normal.

The transistor in both units undergoes an aging process during the first few hours of operation. This process causes the beta of the devices to drop a few per cent. This reduction in gain happens on both repeaters, but is more noticeable on the *AT-3* because of its high impedance output. In all cases, the units stabilize at the end of 24 hours. At present, the transistors are stabilized before being connected into the units by being baked for a period of time at 85 C.

The operation of the repeaters under high transient conditions was further considered. To simulate a high transient, a large capacitor, charged to a potential of more than 1,000 volts, was discharged across the input terminals of the *AT-2* repeater. This unit showed no signs of damage after over 1,000 discharges, whereas a comparable vacuum-tube unit would be inoperative after 10 to 20 discharges.

It might be possible to use an n-p-n and a p-n-p transistor in a complementary symmetry circuit with some simplification; however, matched transistors of the two types with similar operating characteristics might be difficult to obtain. A single-transistor negative-impedance repeater has been successfully tested, but like vacuum-tube circuits with one tube versus those with two tubes in push-pull, greater care was required to prevent signal distortion, and the unit could not handle sufficient output levels before this distortion point was reached.

Under the most favorable conditions the maximum integrated gain of an *AT-2* alone can never exceed approximately 50% of the loss of the line with 10 db as the maximum limit, and the combination *AT-23* repeater can never exceed approximately 85% of the loss of the line with 14 db as the maximum limit. The maximum gain depends upon the length or loss of the trunk or line, its uniformity and the location of the repeater. It is a function of the negative impedance of the series unit, the negative admittance of the shunt unit, and the sums of the impedances of the two lines looking away from the repeater between working and idle circuit conditions. The maximum gain when an *AT-2* alone is used on a loaded line is approximately 8 db. As a terminal repeater the repeater gains are reduced about 20% with a crosstalk limit of approximately 8 db as high. The integrated gain is the insertion gain taken at several points over the voice-frequency range and divided by the number of points; it gives a more accurate picture of repeater performance. A given gain versus frequency characteristics may be reshaped at the lower or upper frequencies by only a minor adjustment of one of the network components without significantly changing the average value of the gain.

The series repeater will perform very satisfactorily alone on a line which is not too long or where the amount of delay (echo) is short. This delay, or echo, is produced when any such device is placed in a smooth transmission line. When the delay is small, as in the case of an interoffice trunk, a large amount of "echo" can be tolerated, but in the case of a toll connection the total delay of many connected circuits may be large and only a small "echo" can be permitted. For these cases the shunt or *AT-3* repeater was designed to be used in conjunction with the series unit. Since the shunt repeater would add shunt negative admittance to the line and the series would add a series negative admittance to the line and the series would add a series negative impedance, the combination would least tend to change the over-all characteristic of the line. The image impedance of the repeater in this case would more nearly match the characteristic impedance of the line. Such a combination repeater would provide approximately the same gain as the hybrid repeater under similar line conditions, and have similar effects on return loss. In very few cases in the local telephone plant would any gain higher than the 14 db possible with an *AT-23* be required.

At the present time about three *AT-2* repeaters are being used to every *AT-23* used. However, it is safe to assume that in the next few years the combination repeater will be employed in the majority of cases.

Because the *AT-2* is in series with the line, this repeater has, in the conventional sense, no input or output impedance and

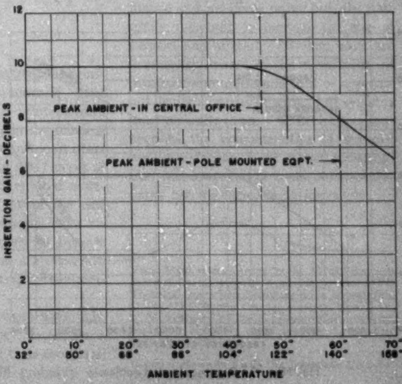

Fig. 8. Effect of ambient temperature change on AT-2

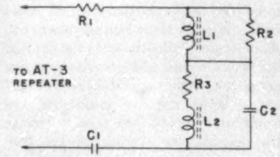
AT-2 LOADED CABLE NETWORK (B)



AT-3 LOADED CABLE NETWORK (C)

Fig. 9. Networks used on repeaters

cannot be correctly tested unless connected to the line in question or a closely simulated condition. The shunt unit has a high output impedance in the vicinity of 8,000 ohms at 1,000 cycles with a resonant frequency of 130 cycles. For those few circuits using 135-cycle signaling the use of an *AT-3* is not recommended. Below 100 cycles the shunt repeater does not load the circuit to any extent, and at 20 cycles the effect is negligible.

The stability of both repeaters against oscillation is obtained by setting the network for gain values which will be stable under trunk or line conditions, and by selecting network values that drop the gain at the low and high end of the band. These units will invariably be stable under trunk or line conditions, if they are stable under idle conditions.

Application

In the 3 years that these repeaters have been in service, they have found a wide field of application in many types of circuits. A few of the more widely used of these applications are as follows:

1. On special service trunks, private branch exchange extensions, and tie trunks.
2. On longer tandem trunks to reduce over-all tandem standards.
3. On tributary trunks where extensive cable is used.
4. On the longer toll connecting trunks.
5. On trunks to centralize intercept and information desks.
6. To equalize and add gain on nonloaded cable in the same manner as is done with the use of loading without touching the cable proper.
7. In some cases on long subscriber lines where cable is used.

Performance

When *AT-2* repeaters are placed in service, two general types of networks are used depending on the types of lines connected to both sides of the repeater, and whatever central office equipment might be connected across the lines at the repeater. Fig. 9 shows these networks. The network in Fig. 9(A) is used when an open wire or nonloaded cable is connected to both sides of the repeater, or an open wire is connected on one side and a nonloaded cable on the other. The resistance *R* and the capacitance *C* determine the approximate over-all gain and frequency equalization. It is possible to change the frequency response of the repeater by selecting various values of *R* and *C*. If some type of long-line adapter, repeating coil, or comparable equipment is located near the repeater, an additional inductance is connected across the network. The performance of a series repeater in an application of this type is shown in Fig. 10. This curve shows how a nonloaded line with its greater loss at the higher frequency end can be equalized directly at the repeater to produce a circuit which, in effect, is similar to that obtained if the line were loaded.

When an *AT-2* is installed at the midpoint of a loaded line, as a terminal repeater at the end of a loaded line, or as an intermediate repeater between a loaded and a nonloaded line, the network shown in Fig. 9(B) is used. Capacitor *C2*, commonly referred to as the building-out capacitor, is determined by the end sections of the loaded line facing the repeater. The inductance *L1* and *L2* and capacitor *C1* comprise a low-pass filter with *R1* as one side termination. This filter determines the manner in which the gain is effected near the cutoff frequency of the line. In cases where a loaded line is connected to one side of the repeater and a nonloaded line to the other side, an additional capacitance *C3* and resistance *R2* are added to handle the nonloaded line characteristics.

An application of this type is shown in

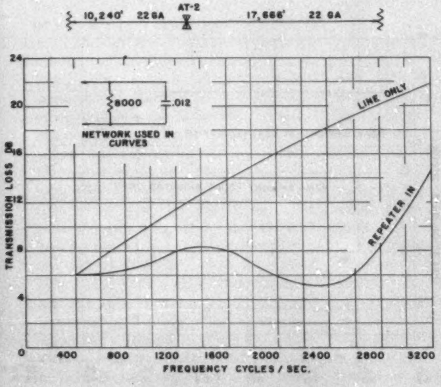


Fig. 10. AT-2 on nonloaded cables

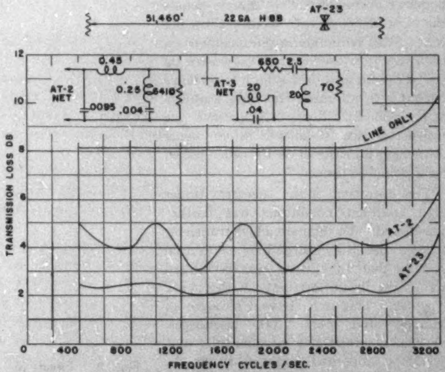

Fig. 11. AT-23 on loaded cable

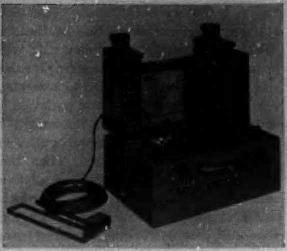

Fig. 12. Installer's set

Fig. 11. Note that the response curve of the series repeater is a series of peaks, which are further accentuated when telephones are used as terminations at each end instead of resistances. These result from variations in line and telephone impedances and make it rather difficult to judge accurately the effective gain of the repeater. When a repeater is properly installed, these variations do not exceed ±2.0 db.

When a combination repeater is required the gain adjustment network of the shunt unit would have a configuration as shown in Fig. 9(C). The capacitance *C1* governs the amount of low-frequency gain, and the inductance *L1*, governed by its shunt resistance, governs the amount of high-frequency gain. The resistance *R1* governs the over-all gain. If the *AT-3* is to be used as a terminal repeater, an additional resonant circuit may be added in series with the network to reduce a peak which sometimes occurs under these conditions. The shunt repeater adds a small amount of gain to the *AT-2* but, more important, it tends to straighten out the response curve.

Installation

It is readily apparent from the previous text that the most difficult part of the installation of a repeater of this type is in selecting a proper gain-adjusting network. When this is found the repeater will require no further attention other than an annual check of the gain of the unit, assuming that the lines have not been altered. This network can be determined by a cut-and-try method with reasonable accuracy; however, to speed up this selection an installer's set was designed to permit one to adjust these various components in the network quickly and accurately. A view of the installer's set with a series and shunt repeater attached, is shown in Fig. 12. By using the necessary oscillator and voltmeter one man can make all adjustments directly at the repeater and measure the final insertion gain of the unit. The use of this set simplifies the installation procedure and enables one person to obtain a satisfactory network in a short time. If a number of repeaters are to be installed on other pairs in the same cable, it is only necessary to determine the network with one repeater, and duplicate the strapping in the other units.

Conclusions

Today, several thousand of these repeaters are giving satisfactory service Some of these units have been in operation continuously for 3 years on their initial transistors. With aged transistors and close tolerance components, present repeaters are quite uniform in gain characteristics.

With small-size and low-power repeaters such as these available, it should be economical to apply them and provide quality transmission on finer gage cable than heretofore was possible. As transmission standards are raised, there may be cases where a still smaller gage trunk with two repeaters will be cheaper than a larger gage circuit with one repeater.

The MITE Teleprinter

BERNARD HOWARD
NONMEMBER AIEE

Synopsis: This newly developed telegraph page printer weighs only 12 pounds, but is completely compatible with existing teleprinter equipment. It is believed to be the first practical teleprinter of radically reduced weight and cube and one of the most radical innovations in the teleprinter art. This paper describes some characteristics of the machine and discusses the basic mechanisms used.

A NUMBER of new "data read-out" devices have been developed in recent years to keep pace with the requirements of automatic digital computers. The outputs have taken the forms of cathode-ray indicators, magnetic tape, punched cards and tape, smoke printing, magnetic printing, and electrostatic printing, as well as alpha-numeric page printers.[1] Page and tape printers have been used for many years in communication circuits and have been made to operate in response to as many as 11 types of Morse, synchronous printer, and start-stop printer codes.[2] Many of the new types of equipment, however, have required special input signals or operate at high rates of speed and are otherwise not compatible with existing communication equipment.

Civilian and military users have indicated that, although they anticipate a need for higher speeds in their communication circuits, they will probably use printers operating from the telegraph start-stop code for some time to come.[3,4] The Armed Forces find it increasingly desirable to add electronic aids to their mobile and air-borne units but are naturally reluctant to increase the size of vehicles and aircraft. Civilian users are increasingly aware of the desirability of printed communications and of a print-out device compatible with those systems most generally in use. In both these connections the characteristics of reduced weight and cube, lower power consumption, and lower initial costs and maintenance become increasingly important.

Paper 58-48, recommended by the AIEE Telegraph Systems Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted September 30, 1957; made available for printing December 3, 1957.

BERNARD HOWARD is with the Teleprinter Corporation, Paramus, N. J.

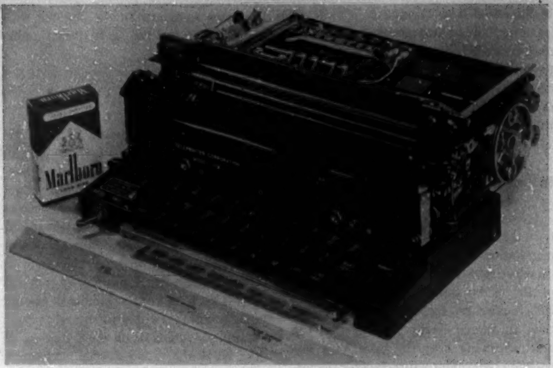

Fig. 1. MITE with keyboard in operating position

General Characteristics

It was with these facts in mind that the "Miniaturized Integrated Telegraph Equipment" (MITE) was developed. The initial machines were designed with a view towards both commercial and military specifications. It is believed that this small, lightweight printer has a place both in communication services and in certain computer applications. It is not intended to compete with high-speed units such as a recently announced digital printer which prints 10,800 lines (the equivalent of an average book) in 1 minute. The MITE is a page printer which weighs 9 pounds when receiving only and 12 pounds when fitted with a keyboard for sending as well as receiving. The printer unit is $3^{1}/_{2}$ by 8 inches by 12 inches. The keyboard unit is $1^{1}/_{2}$ by 8 by 12 inches. The carrying case is 5 by 11 by $12^{1}/_{2}$ inches. The carrying case weighs approximately 4 pounds, so that the complete equipment weighs 16 pounds. Fig. 1 shows the MITE with the keyboard can be pushed back under the printer, or it can be removed altogether as shown in Fig. 2.

The machine operates up to 100 wpm (words per minute) with the standard 7.42-unit Baudot code but future models are expected to operate up to 200 wpm if the code pulses are fed to the machine simultaneously. The machine is completely compatible with 7.42-unit code machines and can be converted in a matter of minutes to 60-, 66-, 75-, or 100-wpm operation by changing one externally mounted gear. Actually there is nothing inherent in the design of the machine which limits it to this type of code and special machines are being built to operate with other codes. Both the keyboard and type cylinder can be changed to accommodate weather symbols, or, in fact, to any desired selection of characters or functions up to a maximum of 64. (Two of these are shift from lower to upper case and the reverse shift from upper to lower.)

A New Approach to Character Positioning

One of the design objectives was to produce a machine capable of high-speed operation with a minimum of high-speed mechanical motions. This demanded a radically new approach to the method of deriving 64 mechanical positions from the five intelligence pulses in the start-stop code.

One of the basic principles used in the MITE is illustrated in Fig. 3. This uses a unique application of one of the six "simple machines," the pulley. It will be seen that if one end of the string is fixed and the other end is attached to a weight, a 1/2-inch movement of any pulley in a vertical direction will move the weight 1 inch. Next, suppose that each pulley is moved a different distance. Then the weight can be moved to any one of five different positions, depending on which pulley is moved. Finally, consider the possibility that each pulley is moved from its resting position twice the distance that the previous pulley travels and consider, also, that from one to five pulleys are moved at the same time. It can now be seen that there are 32 evenly spaced positions of the weight for all of the possible combinations of pulleys moved or not moved.

If a strip of type is substituted for the weight, then an elementary character-positioning device will have been provided. The 32-character length of the strip would, however, require a rapid motion of the type strip if the first and last letters on the strip were called for sequentially.

The space and motion requirement could be reduced by arranging the letters in the form of a rectangle eight characters long and four characters high and employing two co-ordinate motions. The space and motion requirement could be still further reduced by folding the rectangle into a half-cylinder eight characters long and with four faces and converting the linear co-ordinate motion used to choose one of the four up and down positions of the rectangle to rotary motions up to 180 degrees. This has been done in the MITE with an 8-sided type cylinder which is eight characters long; see Fig. 4.

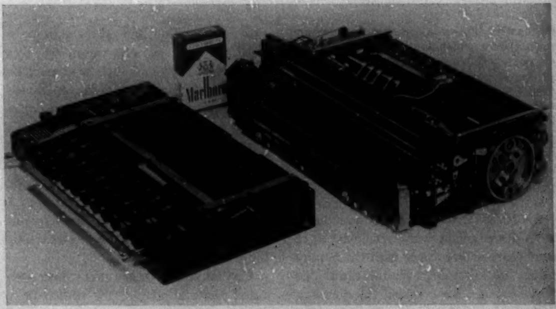

Fig. 2. MITE with keyboard removed

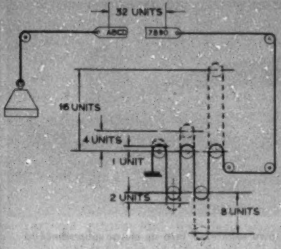

Fig. 3. Schematic of a simplified print-positioning device

The 32-position half-cylinder derived from the 5-pulley system is represented by four faces of the 8-sided cylinder and eight lateral positions along those faces. The opposite four faces of the cylinder and the eight lateral positions along those faces represent the upper case of the 32 basic positions so that the cylinder is rotated 180 degrees by the selection of letters or figures (lower or upper case) and the selection within that 180-degree segment is achieved by the basic 5-pulley system. Since a space is designated on the cylinder for every character or function that can be selected, the cylinder provides for 64 possible characters and functions, two of which are letters and figures. In this way a small cylinder can accommodate 64 characters of standard teleprinter type. In operation the first two of the five intelligence code pulses control the rotary selection motions of the type cylinder while the last three pulses control the lateral motions.

The Selector

The problem of arranging for the proper pulley to respond to the appropriate signal pulse is met by the selector in conjunction with motor-driven camshafts.

SYNCHRONIZATION

Synchronization of the MITE printer with the transmitted signal, as with other 7.42-unit code printers, makes use of two pulses. These are referred to as the "start" and "rest" or "stop" pulses. The start pulse effectively starts the rotation of the timing camshaft by releasing the start clutch. The rest pulse, which is 1.42 units long, occurs between the fifth signal pulse and that start of the next start pulse and allows a margin of error to exist between the motor speeds in the sending and receiving machines. The receiving camshaft rotates faster than the corresponding transmitting camshaft and comes to a stop during the stop pulse while the transmitting camshaft will rotate continuously during a continuous automatic transmission such as from a tape transmitter.

REDUCTION OF MECHANICAL SPEEDS AND LOAD

In the MITE, the mechanism which controls the pulleys, and consequently the type cylinder, is arranged to reduce the speed of operation and mechanical load on the machine by gradually positioning the type cylinder while the signal pulses are being received rather than by storing the pulses mechanically as they are received and beginning the positioning of the type after the receipt of the last intelligence pulse. For this reason, and because the type cylinder is located behind the printing medium, there is no need for a neutral position of the type cylinder; and consequently, in the case of a repeated character, the pulleys and cylinder do not move.

SELECTION

Each of the five type-positioning pulleys described in the foregoing is positioned by a cam follower passing through the pulley housing. The cams which move these followers are each coupled to a clutch. The five clutches and their cams are mounted on a continuously driving shaft on which the clutches free-wheel when not engaged and to which they are capable of being sequentially coupled.

In response to its signal as received by the magnetic selector, each clutch will either engage the driving shaft for a 180-degree rotation or hold its position. The action of the clutch in each case depends on whether a mark or space signal is received and whether the clutch was left in mark or space position by the previous selection. If, for example, the no. 1 pulse for a given selection is a mark pulse, and if the no. 1 pulse of the preceding selection were a mark pulse, the no. 1 clutch will remain stationary. If a spacing pulse is received for no. 1 and the preceding no. 1 was a mark, the clutch will engage for a 180 degree rotation turning the cam affixed to the clutch correspondingly. The cam follower and the pulley controlled by it will go the second of their two possible positions.

The actual release of each clutch is controlled by a pair of levers, one of which will engage the clutch and the other of which will stop it after 180 degrees. Each pair of levers is controlled by the selector and the instant of their release is determined by a sequence shaft which starts rotating upon receipt of the start pulse. The control of the clutch releases by the sharp drops in the sequence shaft cams is a feature which contributes markedly to accurate response and good range in the receiver.

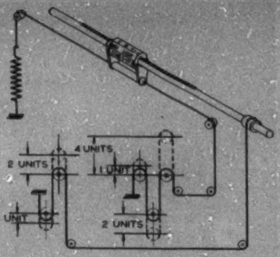

Fig. 4. Schematic of print-cylinder positioning method used in the MITE

At the end of the receiving cycle the sequence camshaft rests while the main driving shaft on which the five pulley clutches now free-wheel continues to turn. The rotation of the main shaft after the receipt of the fifth intelligence pulse releases the special function causing mechanism and either performs a mechanical function when one is selected or releases the print hammer to complete the character cycle.

RANGE ADJUSTMENT

The relative time at which the magnet armature position is sensed can be adjusted by moving the angular position of the timing camshaft with respect to the point at which the camshaft is released by the start clutch. This angular position of the start clutch release mechanism is connected to a calibrated dial which is marked in terms of percentage of one signal pulse. The variation in angular position which is possible without mutilation of a message is known as the "range" of a teleprinter. The MITE has regularly been observed operating with ranges in excess of 75 points at 60 wpm in the laboratory, and has tolerated signal distortions in excess of 35 points under the same conditions. This range adjustment permits the printer to operate correctly from distorted signals such as may be received over long telegraph lines.

Keyboard

GENERAL

The mechanical and electric connections between the keyboard and the printer are very simple. The keyboard

Fig. 6 (above). Printer, keyboard, and paper roll shown mounted on a chassis

circuit is in series with the printer signal circuit and when the keyboard is removed from the printer or put in storage position, the contacts on the printer are automatically short-circuited. A spur gear couples the printer motor to the keyboard operating shaft. The keyboard can be operated separately as a unit remote from the printer by use of a separate motor. The keyboard operates as follows: The striking of any key, or the space bar, releases a clutch which permits the motor-driven keyboard camshaft to make half a revolution. At the same time five code bars are set up in a particular sequence according to which key is struck. These code bars will permit or block the motion of a series of cam follower levers, which in turn will permit a series of five contacts to make contact or stay open and thus transmit the proper signal. The contacts are in series with the signal line and when no keyboard key is pressed, the contacts are closed.

REGULATION OF TRANSMISSION

In order to transmit the correct signal, these contacts must make and break at particular times, which would normally require a very accurate adjustment of each contact. This is avoided by providing a master pulsing cam on the keyboard camshaft. This operates a pair of contacts which accurately determine the timing of transmission while the five contacts affected by the code bars only determine whether or not each of the pulses is transmitted. The stop on no. 2 and no. 4 contacts are connected to one of the pulsing contacts and the no. 1, 3, and 5 contacts are connected to the other pulsing contact. In this way the adjustment of the five contacts is made noncritical and only the single pair of master pulsing contacts requires adjustment.

Motors

The rotational inertia of the motor serves to integrate the pulses of mechanical power required for the printing cylinder positioning operations over the full character cycle. As the total power required by the machine is 25 watts including the power for operation of the magnets, quite a small motor is used. When the power source is a-c, the motor operates at 3,600 rpm for 60 cycles per second and 12,000 rpm for 400 cycles per second. These motors are synchronous with the line frequency and no speed adjustment is possible. When the power source is d-c, a 10,000-rpm motor is used and an adjustment governor is used for speed adjustment. A 101.69-cycle tuning fork is used for speed-adjustment purposes. The motor speed is the same for all operational speeds, a single gear being changed for the various sending and receiving speeds. (The 25-watt figure given was observed with the d-c power source and the a-c figure may be somewhat higher.)

Printing Out

PAPER-TYPE RELATION

The type cylinder prints from behind the paper and the print hammer presses the inking ribbon against the front of the paper. This unusual arrangement maintains the type face clean at all times and also has the advantage of reducing mechanical wear on the inking ribbon which is struck by the smooth, regular hammer face rather than by a sharp, irregular type face. The main advantage is that the operator has greater visibility of the printing as it is being received. A standard typewriter inking ribbon is used. The ribbon tilts back and downwards after each operation of the print hammer so that the last letter printed can be read. The placement of the type does not affect the ability of the printer to make carbon copies.

CARRIAGE RETURN

Unlike an ordinary typewriter, the paper does not move laterally but only the type cylinder moves. However, the term "carriage return" is still used. Since the type cylinder is quite light (about 1/2 ounce), fast return action is possible. This is important to ensure that the first character at the beginning of the new line is to be clear when only one character space is allowed for the carriage return operation. The MITE is fitted with automatic carriage return and line feed which are triggered when the end of a line is reached without receipt of carriage return and line feed signals. The MITE prints 72 characters per line on standard $8^{1}/_{2}$-inch rolls.

Nonprinting Functions and Special Outputs

The nonprinting functions of the machine include all standard communication printer functions such as carriage return, line feed, shift, signal bell, repeat key, and the break key. Four of these functions can be directly controlled mechanically from front panel buttons. These buttons will not put a signal on the line but can cause the following operations: carriage return, line feed, figures, and letters. In addition, auxiliary outputs can be provided for special functions.

In series with the two pulley-controlled cables which position the type cylinder rotatively and laterally are two slotted plates which slide laterally parallel to one another. The arrangement of the slots in these plates is such that the selection of a nonprinting function will align a certain pair of slots in the two plates. A series of function clutch release levers attempts to sense the alignment of any two slots during each character cycle. When the slots are not in alignment, the levers are deflected. When a nonprinting function signal is received, the appropriate lever is not deflected, but passes through the aligned pair of slots releasing its clutch. These slotted plates can easily be adapted with additional slots and function clutch release levers and clutches, so that additional nonprinting functions can be provided for. There is a position on the type cylinder for each of these functions. Normally, in these positions there is no character on the type cylinder and the print and character advance functions are suppressed. A character could, however, be printed simultaneously with the introduction of a special function if so desired.

In addition, there are about 30 points in the MITE at which contactors, mechanically actuated by the machine, can be installed. These contactors can be used to set up electric circuits in combinations determined by the characters or groups of characters selected by the MITE.

Design and Construction

Design

Certain basic design principles were adhered to in designing and developing this equipment. While miniaturization of the over-all machine was a basic goal, the utilization of full-size components was considered a necessity. The miniaturization of the machine is, therefore, a result of its simplified design and of new approaches to certain problems which permitted that simplification.

Reduction of mechanical speeds within the equipment was considered paramount as was reduction of distances travelled by moving parts. Rotating components were considered preferable to reciprocating components and the weight of moving parts has been kept at a minimum.

The MITE has been designed so that gravity restoration is avoided, permitting operation of the machine in any attitude including upside down. While the standard carrying case accommodates the printer and keyboard, a standard full-size roll of paper, spare parts, and field service tools, other special cases are being developed. The standard roll is $8^{1}/_{2}$ inches wide and $4^{1}/_{2}$ inches in diameter. The machine lends itself quite readily to rack mounting either while still in the carrying case or after removal from it.

Unitized construction was adopted to permit complete replacement of whole sections. Fig. 5 shows the machine broken down into its main subassemblies. These are, from top to bottom, the ribbon magazine, the printer section, main shaft, and the selector section. The breakdown into subassemblies is accomplished with the removal of eight screws and requires less than 10 minutes. The reassembly requires less than 20 minutes. All parts are readily accessible for inspection, lubrication, and servicing. It is estimated that personnel with previous experience in servicing teleprinter equipment can be taught to serive this machine in about 1 week while personnel experienced with typewriters and other business machines can be taught in 2 weeks. There are a total of approximately 70 mechanical adjustments on the machine, many of which are one-time factory adjustments to take up tolerances and which do not require readjustment in the field.

In Fig. 6 the printer, keyboard, and paper roll are shown mounted on a chassis.

Materials

The selection of materials used in construction is in keeping largely with military requirements. Special attention was devoted to those parts where there was a possibility of wear and carboloy inserts were used where necessary. The main structural members are stamped aluminum. Precision castings were used where difficult machining operations could be reduced. Considerable effort was required to determine the most suitable material for the cable in the cable and pulley mechanism.

Many types of chain and metallic cable were tried before it was found that the best material was synthetic fiber cable. This was checked in a test jig for 3,000,000 operations using a test which caused stainless-steel cable to fail after 3,600 operations. After the 3,000,000 operations, there was only minimum evidence of wear.

Companion Devices

Other apparatus under development as companions to the MITE include a miniaturized transmitter-distributor and a reperforator. A stunt box which delivers electric outputs upon certain signals or combinations of signals will also be built as a separate item, independent of the adaptations referred to in the foregoing.

The transmitter-distributor which automatically transmits signals when fed with standard 5-hole perforated tape, will weigh less than 2 pounds including the motor. If the unit is to be used in conjunction with the printer, a common motor will be used and the printer motor will have adequate reserve power to drive the tape transmitter. This additional section will add about 1 inch to the width of the printer and 7 ounces to the weight.

Function Tables in Digital Control Computers

E. J. SCHUBERT
ASSOCIATE MEMBER AIEE

Synopsis: Function tables of limited size in connection with appropriate interpolation techniques offer considerable advantages in digital computers used in the control loop of servo systems. Several pertinent applications are treated in detail.

RECENT ADVANCES in the art of data storage devices indicate that compact and inexpensive diode matrices or other random access memories will be available in the near future. This revision of present computing and programming techniques is based on this assumption, with the emphasis on stored digital functions.

The concept of stored function tables is not new but, at the present, it is limited to large computer installations with relatively slow access. In this investigation, digital computers in servo loops of weapon systems are treated, primarily considering the severe limitations in computing time and space.

Without dealing with the details of the function table from a hardware point of view, the general feature of the matrix or random access memory under consideration must be that the argument is the address into the decoder matrix, and the stored function can be obtained directly from the encoder without any searching.

Bilog Function

Straight binary notation is predominant in control computers because of the simplicity of the arithmetic and the economy in data storage. There is only one major disadvantage; the variation of significant bits with the magnitude of the expressed quantity. In several cases, this feature is pertinent as in proximity approach, where the quantities vary over several powers of two. In order to maintain a minimum accuracy, a much longer word has to be provided containing a considerable number of ZERO's preceding and following the significant bits. The conventional remedy is scaling or floating radix point, but this technique causes considerable difficulties in control computers, particularly in logic and programming without much gain in computing speed.

A radical solution in this direction can be achieved by using suitable logarithms because of the great savings in computing time and programming for problems of greater complexity. In this case it is possible to justify the scaling operation, if the characteristic of the log is obtained simultaneously.

A floating binary point implies the relation

$$N=2^{s}(1+a_1(2^{-1})+\ldots\ldots+a_n(2^{-n})) \qquad (1)$$

According to this definition, which deviates from the normalized form (e.g. as used in a Remington *1103A*), the quantity N is represented as

$$N=2^{s}F \qquad 1\leq F\leq 2 \qquad (1A)$$

where s is called the characteristic and F is called the fraction. The bounds 1.000 and 2.000 for F are proposed in order to deal with positive mantissas only, in converting N into its log.

$$\log_2 N=s+\log_2 F \qquad (1B)$$

$$M=\log_2 F \qquad (1C)$$

This logarithm of base two expressed in binary notation is the bilog. To compare this concept with straight binary routines depends primarily on the size of the function table.

Taylor's formula with the Lagrangian form of the remainder applied for a bilog function becomes:

$$\log_2(X+x)=\log_2 X+1.44\,x/X-0.72\,x^2/X^2 \qquad (2)$$

The last term must be less than the least significant bit 2^{-n}:

$$0.72\,x^2/X^2\leq 2^{-n}$$

For $X=1.00$ the error would be the maximum and accordingly

$$x\leq 1.18(2^{-n/2}) \qquad (3)$$

This equation is certainly satisfied again for a difference $x\leq 2^{-n/2}$.

In a computer with 16 bit words, the first bit is reserved for the sign and at least three more for the characteristic s. Therefore not more than 12 bits are available for the fraction F. For $n=12$, the increments $x=2^{-6}$ would be small enough for the accuracy specified. In this case, function tables with $2^6=64$ entries suffice.

For the value of X causing the largest error, the numerical interpolation is shown in Table I, wherein octal notation is used instead of binary and denoted by (o). This largest error, shown in Table I, satisfies the condition to be less than the least significant bit 2^{-12}.

From Table II it is seen that the gain in computing time with bilog code increases clearly for higher complexity of the arithmetic operations, particularly if antilog operations are not necessary between individual operations.

Scaling

To scale a binary word into floating notation requires a shift operation to position the most significant ONE with respect to the radix point proper. Instead of shifting the word, the ZERO's preceding the most significant ONE may be sensed and read through a matrix to form the characteristic s. The following relation governs this operation, irrespective of the accuracy:

b = total number of bits in the word $=2^{c}-1$
s' = number of ZERO's preceding the most significant ONE
p = number of bits right of the binary point
s = characteristic as defined in equation 1 requiring c bits

$$s=(b-p-1)-s' \qquad (4)$$

The term in brackets is a constant for the particular digital system. This concept is best illustrated for a typical system, wherein N is represented in several notations as marked.

(d) = decimal
(o) = octal
(b) = binary

$$N=41.75(d)=51.60(o)=101\ 001.110\ 000(b) \qquad (5)$$

Table I. Numerical Interpolation of $\log_2$ 1.0154

	a(o)	b = a	c = log₂b
X	1.0000(o)	1.0000	0.0000
X	0.0077(o)	0.0154	0.0222 = 1.44 x/X
X+x	1.0077(o)	1.0154	0.0220 = true value
	error $2.10^{-4}=0.000064$(o) ≤ 0.0001(o)		

Paper 58-231, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted September 5, 1957; made available for printing February 10, 1958.

E. J. SCHUBERT is with the Burroughs Research Center, Paoli, Pa.

In the straight binary notation, 16 bit words are used; the first bit containing the sign, the binary point in the center of of the word.

$b=15;\ p=8;\ 2^c-1=15\ldots c=4$ (5A)

Hence four bits have to be reserved for the characteristic s with 11 bits remaining to convey the fraction F.

$N=0\ \underline{1}01\ 001.110\ 000\ 00$

$s'=1;\ s=(15-8-1)-s'=6-1=5$ (5B)

$N=2^s(1.30468(d))$ (5C)

As defined in equation 1(A) the fraction F is always greater than 1.00, therefore, there must be always a ONE preceding the radix point. This most significant ONE marked as $\underline{1}$, is therefore a redundant information and may be deleted to increase the number of significant bits to twelve. To discriminate this notation from others, the term "compressed data" is used together with a # to separate the characteristic from the abridged fraction F-1.

$N=5/2340(o)$
$=101\#010\ 011\ 100\ 00(b)$ (5D)

In addressing the bilog matrix, F-1 is required only, and will be substituted by the mantissa M. The characteristic s, which is retained in the word $\log_2 N$, is left from the suppressed ONE #.

Sine-Cosine Tables

A table with a limited number of entries comprises the functions sin X and cos X with full accuracy. The content of the function table are the main values for the range $0 \leq X \leq \pi/4$. For arguments different from the main value X, the functions are interpolated.

In order to determine the number of entries required to interpolate the functions with N significant bits, the Lagrangian remainder in Taylor's formula must be less than the least significant bit.

$\sin(X+x)=\sin X+x(\cos X)-0.5x^2(\sin X)$ (6)

For the value $X=\pi/4$ the last term becomes a maximum.

Table II. Comparison of Binary and Bilog 16-Bit Arithmetic

	Binary	Bilog	Remarks
Sign bit	16th	16th	identical
Range of integer	2^0 to 2^7-1*	2^0 to 2^7 (3 bits)	* binary point between bit 8 and 9
Accuracy	varying 8 to 15 bits	constant 12 bits	
Add/Subtract	1 minor cycle	2 minor cycles	
Multiply	2 minor cycles** 15 minor cycles	6 minor cycles	** whiffle tree
Divide	15 minor cycles	6 minor cycles	
Square root	40 minor cycles	4 minor cycles	

Table III. Numerical Interpolation for Sin 45 Degrees From the Main Value for 44.2 Degrees

	a(o)	b=a	c=πb/4, Radians	d=45.b, Degrees	sin	cos
X	0.7700(o)	0.98438		44.32	0.6986	0.7160
X	0.0076(o)	0.01513	0.01190	0.68	0.0086 = x(cosX)	
φ=X+x	0.7776(o)			45.0	0.7072	
	true value				0.7071	
error 0.0001=0.000032(o)<0.0001(o)						

$\sin \pi/4=0.707$

$0.5x^2(0.707)=0.35x^2 \leq 2^{-n}$ (7)

$x \leq 1.68(2^{-n/2})$

The last equation is certainly satisfied for the difference

$x \leq 2^{-n/2}$ (8)

Accordingly the function table must have $2^{n/2}$ entries. For an argument with 14 bits corresponding to the full angle, the first 3 bits denote the octant only leaving 11 bits for the information $X+x$.

If the argument within the octant comprises 11 bits, then $n=11$, and x must be limited to the least 5 bits. The remaining six bits of the argument belong to the mainvalue of X, to be obtained from a function table with $2^6=64$ entries.

This surprisingly low number of words in the permanent storage suffices as demonstrated for the largest error as shown in Table III. As a matter of convenience, octal notation is used instead of straight binary and denoted by (o) in column a.

Referring to the example mentioned in the preceding with an argument of 14 bits, the most significant 3 bits select the sign of the outputs and control the access to the twin matrix according to Fig. 1 and the following program for $\sin\phi=\sin(X+x)$,

1. Transfer ϕ into address register A with x overflowing into arithmetic unit M.
2. Read cos X from twin matrix T into arithmetic unit M via B.
3. If applicable form lower product x(cos X) and discard.
4. Form higher product x(cos X) and add to sin X read out from T via B.

The program is based on a serial machine with a shift register A and B suitable for serial and parallel in- and outputs. Furthermore, the A-register may complement the content X if so instructed from the control matrix C, according to the octant represented in the three most significant bits of A.

Arc Tan Table

Another application for a rather complex function is the computation of arc tan Z in real time following the cartesian co-ordinates of a flying spot. Two methods are applicable depending on the bounds for x, y. The first method applies for the whole range within the upper and lower bounds $\pm 1/2$ and requires the term $Z=Y/X$, for a spot moving in the direction Y and advancing at the end of this scan in the X direction for one increment only. Within a single line, the X co-ordinate is constant and therefore, the change of Z is limited to the partial differential with respect to Y.

$z=dZ=dY/X \quad \text{for } dX=0$

$Z+z=(Y+y)/X$

Applying Taylor's formula for the single variable Z yields:

$\arctan(Z+z)=\arctan Z+z/(1+Z^2)-z^2Z/(1+Z^2)^2$

The last term corresponds to Lagrangian's remainder with the maximum error at $Z=1.0$ to be less than the least significant bit 2^{-n}.

$z^2(1+z)/(1+(1+z)^2)^2=z^2/2^2(1+z) \leq 2^{-n}$

$z \leq 2^{1-n/2}$

For a range of $\pm 2^{-1}$ for X, Y with an accuracy of 10 bits, the arc tan might be required with 14 bits. The computation of arc tan is performed within one octant only, and the octant itself is denoted by the signs of X, Y, and their relative magnitude. Using three bits for the octant leaves 11 significant bits, correspondingly $n=11$.

$z \leq 2^{-5.5}$ is satisfied for $z=2^{-6}$

hence the range of Z between 0 and 1.00 must be available in 64 main values or in steps of 2^{-6} to achieve the required accuracy.

Fig. 2. Function of two variables

Interpolation is similar to the previous table using an auxiliary matrix for the term $(1+Z^2)^{-1}$ addressed from the same decoder as the main table.

The second method eliminates the periodic division of Y by X in a modification of the Taylor's series for two variables. There is one serious limitation of this more direct approach, the error in vicinity of the origin is excessive. But there are several applications, where data processing might be excluded from this range.

Functions of Two Variables

Instantaneous co-ordinates of the spot are given in x, y, within the bounds $\pm 1/2$. The spot moves from the lower bound in x, to the upper bound in increments of the least significant bit to write a single line. After completing one line, the y coordinate changes for one increment to the adjacent line.

Using Taylor's series again for the appropriate approximation yields:

$$\text{arc tan } (Y+y)/(X+x) = \text{arc tan } Y/X + (Y(x)-X(y))/(X^2+Y^2)+R \quad (9)$$

The last term R is the Lagrangian remainder and determines the number of entries for the mainvalues of X, Y. Instead of calculating X/Y, a matrix with double entries in X and Y is used as decoder and control. Considering the first octant, the flow of pulses corresponding to steps in x increments is accumulated in a binary counter to store $X+x$. The capacity of this counter is 1; accordingly an overflow signal occurs at the upper bounds $+1/2$ and serves as incremental input in the $Y+y$ counter. Three function tables are suggested to reduce computing time according to the following equation:

$$\text{arc tan } (Y+y)/(X+x) = \text{arc tan } Y/X + x(Y)/(X^2+Y^2) - y(X)/(X^2+Y^2) \quad (9A)$$

If speed is a premium, digital integrators are most convenient in connection with the stored function. The first term on the right is the initial condition z_0 of the integrator x, the second term governs the dz/dy integrator, and the third term corresponds to the dz/dx integrator. Counters for X and Y may be substituted by similar integrators controlling the function table. In the conventional symbols for differential analyzers, the block diagram is depicted in Fig. 2. Use of a common high-speed arithmetic programmed to handle data in a random access memory may be applied in larger systems.

In this example, the registers perform linear integration within the bounds set by two adjacent mainvalues as stored in the function table. Initial condition z_0 is extracted from the function table and the two differences dz/dx and dz/dy are added. As soon as the next mainvalue in X or Y has been reached, the content of the z register is discarded and substituted by the accurate initial condition for the new mainvalue. Therefore, accumulation of errors in the z register is inhibited.

Design Equations

To determine the specification of the function tables for the design of a system the following approach is suggested.

Any function $f(X+x)$ may be generated in the manner outlined before providing the argument $X+x$ forms the address into a decoder in such a way that the m bits corresponding to X only are retained in the address portion of the register A, Fig. 1. The function table in the twin matrix T comprises a decoder selecting one-out-of-2^m words contained in the encoder section. This concept is based on uniform increments corresponding to the lowest bit of the address X and nondestructive storage facilities for $f(X)$ and $f'(X)$:

$$f(X+x) = f(X) + x(f'(X)) + x^2(f''(X)/2) \quad (9)$$

With proper scaling the argument X may be restricted to the bounds $+1$ and -1 comprising n significant bits. Linear interpolation will be satisfactory providing the last term in equation 9 is less than the least significant bit 2^{-n}. This condition is certainly satisfied for

$$x^2(f''(X)) = 2^{-n} \quad (10)$$

$$\log_2 x = -n/2 - 1/2(\log_2 f''(X) \quad (11)$$

$$2^m = x(2^n) \quad (12)$$

Hence the number of 2^m words required in the function table is

$$m = n + \log_2 x = (n - \log_2 f''(X))/2 \quad (13)$$

$f''(X)$ should be an extreme within the bounds. The value of $f''(X) = 0$ is irrelevant and indicates straight line intervals. Any symmetry may be utilized in reducing the size of the permanent storage by appropriate control as shown by means of the control matrix C in Fig. 1 depending on intervals of the argument in the A register.

In the subroutine for the interpolation the difference x from the mainvalue X is of concern and might require up to d bits.

$$d = n - m = (n + \log_2 f''(X))/2 \quad (14)$$

Based on the derived expressions the size of the storage facilities can be specified as follows:

1. Address into the decoder section: m bits; equation 13.
2. Storage capacity for mainvalues $f(X)$ disregarding scale factor and sign: 2^m words with n significant bits each.
3. Storage capacity for the first derivative $f'(X)$ if applicable 2^m words with d significant bits each; equation 14.
4. Control matrix for switching certain intervals of the argument depending on the symmetry of the function within the chosen bounds.

Some Measurements of Abnormal Corona

GAYLORD W. PENNEY
FELLOW AIEE

JACK G. HEWITT, JR.
ASSOCIATE MEMBER AIEE

CORONA is universally used for charging particles in electrostatic precipitation. In normal corona there is a glow at the active electrode, usually a wire, which supplies ions of one sign to the main charging region. Under some abnormal conditions a glow may exist at points away from the active electrode so that there are ions of both signs in the charging region. These abnormal conditions usually increase the current at a given voltage, and may be quite detrimental in the charging of dust particles. Two types of abnormal corona have been investigated.

The first type of abnormal corona investigated may occur when the active electrode is positive. Insulating material on a positive active electrode may result in a glow which extends out a considerable distance, particularly if the active electrode is large (e.g., 1/8 inch to 3/16 inch) in diameter. This type of abnormal corona will be called a "flare" because of the appearance of the glow. The types of flares discussed in this paper are not intended to represent any particular condition in a normal precipitator. However, it is possible that the same mechanism occurring on the passive positive electrode may be responsible for initiating flashover under many operating conditions. This part of the study was, however, intended only to give a better basic understanding of corona and is not related to any commercial application.

The second type of abnormal corona is due to high-resistivity dust on the large or passive electrode. This produces a glow at the large electrode and results in ions of both signs throughout the charging region and may greatly reduce the charge acquired by particles.

Apparatus and Experimental Procedure

Since the purpose of corona is to charge dust particles, the charge acquired by particles is an excellent means for evaluating corona. For this reason the charge acquired by metal spheres was one of the main tests used. Curves of current versus voltage are another important means for evaluation. Where ionization of air is taking place, visible light is usually emitted. This may be of such low intensity that it is difficult to observe by eye but photographs of corona taken in a darkened room can reveal the location of any glow. Such photographs were therefore used in this study. In order to charge particles effectively corona must have ions of only one sign, the same sign as the wire or active electrode. Ions of a sign opposite to the polarity of the active electrode are very detrimental to the charging process since such ions tend to neutralize the charge on particles. A test for ions of the wrong sign is therefore important in studying any abnormal corona. This test for ions of the wrong sign was made by charging a steel ball with a charge higher than could be acquired from the corona being studied. This highly charged steel ball is then dropped through the corona being studied.

Paper 57-87, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., January 21–25, 1957. Manuscript submitted November 15, 1956; made available for printing November 13, 1957.

If there are no ions of the wrong sign, no loss of charge will occur; conversely, if there are ions of the wrong sign, the charge on the steel ball will decrease markedly.

The principal parts of the apparatus are shown diagrammatically in Fig. 1. The small or active electrode for producing corona consists of a wire or rod mounted along the axis of a 9-inch-inside-diameter cylinder. This 9-inch cylinder serves as the large or passive electrode and consists of a central section 1 foot long connected to a ground through a meter and two end sections which are grounded and serve as guard sections. The central wire or active electrode is supported by insulators and connected to an adjustable-voltage d-c source capable of supplying up to 70,000 volts.

To measure the ability of corona to charge particles, steel balls can be dropped through the corona and caught in a metal cup connected to an electrostatic voltmeter. A grounded metal shield is mounted over the cup to shield the cup from any ions which would otherwise impart a stray charge to the cup. Since the time of fall is relatively long, the charge acquired by the steel balls is substantially the maximum or equilibrium charge. When one knows the equilibrium charge, the field strength can be computed.

This method is somewhat similar to the method used by Cooperman[1] who shot balls at two different velocities and used the resulting data to compute both field strength and current density. In the tests reported here the balls were merely dropped from a height of a few feet which for most cases gave a time of fall which was long as compared to the time to reach the equilibrium charge. This procedure gave more consistent results than did the measurement of the charge acquired by high-velocity balls. However, at high voltages there is some tendency to deflect the ball horizontally; this deflection may be of the order of 0.25 inch at the bottom of the cylinder. But this large deflection would occur only at high field strengths in which case the equilibrium charge is reached very quickly and before any appreciable deflection occurs. Thus, provided the field strength does not increase with radius, the deflection will not produce a serious error if the radius recorded is that at which the ball enters the corona.

The theory for charging spherical particles[2,3,4] indicates that the charge is proportional to the electrical field strength multiplied by the square of the radius of the particles. This theory applies from 1 micron up to a size which materially distorts the electric field. In these tests 3/16-inch-diameter steel balls were used. This size was selected as being large enough so that the balls would drop nearly vertically through the corona region and so that the charge collected would be readily measurable, and yet small enough so that the distortion of the field would not be serious. Near the top of Fig. 1 a "precharger" is shown. This consists of a wire mounted on insulators parallel to a grounded plane electrode. Sufficient voltage can be impressed on this precharger to charge the ball to a higher value than that which could be given by the corona to be studied. This precharge can be measured by dropping the ball with the precharger energized but with no voltage on the wire in the 9-inch

cylinder. If energizing the corona region being studied decreases the charge on the ball, this indicates that ions of the wrong sign are present.

Abnormalities in Positive Corona: Flares

Positive corona as used in the low-voltage 2-stage precipitators is normally a glow along the length of the wire. However, occasionally the characteristic of the discharge may change. A rather faint glow, usually bluish in color, will extend away from the wire. This type of glow will be referred to as a "flare" because in the photographs the glow seems to flare outward from a point on the wire. In cleaning air for ventilating purposes these flares are very objectionable because the ozone generated may be many times that of the normal discharge. Also, wherever there is a glow, one suspects that ions are being formed so that there may be an appreciable number of ions of the wrong sign which would result in poor charging of particles. It seemed desirable to investigate the ability of such flares to charge particles. Furthermore, it is thought that these flares may be responsible for the low breakdown voltage frequently associated with positive corona.

Flares may occur because of some mechanical projection or because of insulating material on the wire. Those starting from insulating material show interesting characteristics; particularly when the active electrode is from 0.1 to 0.2 inch in diameter, the flares originating at the edge of insulating material may give much larger currents than will clean electrodes. It is also easier to obtain reproducible results with these large electrodes than it is with the fine wires usually used in the 2-stage low-voltage precipitators.

This study of flares was carried on to obtain basic information and does not represent any particular operating condition. It is hoped that this and further work may help to explain the low breakdown voltage frequently associated with positive corona, as well as other operating peculiarities.

The visual character of flares can be shown by photographs in a darkened room. To obtain better photographs the high-potential wire was located between two relatively large coplanar cylinders. This arrangement is shown in Fig. 2 with the field of view of the camera shown by the dotted rectangle. Photographs of positive corona are shown in Fig. 3. The uniform corona at 48 kv positive obtained

when the wire is clean is shown in Fig. 3(A). Fig. 3(B) shows the pronounced flare at 26 kv produced by a band of insulating material around the wire. In Fig. 3(C) the voltage is raised to 35 kv and the flare has spread across to the opposite electrode. This is very close to flashover. A comparison with Fig. 3(A) for a clean electrode at 48 kv shows the effect of insulating material in reducing flashover voltage in the case of positive corona. Fig. 3(D) shows the much smaller disturbance caused by a band of insulation if the wire is fine. In this case the normal corona resumes relatively close to the band of insulation whereas with a 0.125-inch-diameter wire, the band of insulation eliminates the normal corona for the entire field of view of the camera. Note that, in the arrangement of electrodes photographed, the distance from active to passive electrode is only 2.5 inches as compared to 4.5 inches in the concentric arrangement used to obtain curves of current as a function of voltage.

Fig. 4 shows negative corona first for a clean active electrode and second when there is a band of insulation on the active electrode, at 48 kv. The glow is not smooth in either case but the insulation causes a relatively small disturbance and the discharge is still stable at 48 kv whereas positive corona would have flashed over in the region of 32 to 36 kv.

The flares produced by a layer of insulation on the positive active electrode usually produce a large increase in current as compared with the current for clean electrodes. There is a pronounced hysteresis, the current being higher when the voltage is decreasing. The flashover voltage is relatively low as compared to that for clean electrodes. These characteristics are illustrated in the curves of Figs. 5 to 8.

Volt-ampere curves were taken for a variety of conditions with the intent of gaining an understanding of the nature of active electrode abnormal corona. First, various materials were tried in an effort to discover a dependence on material properties. Second, different shapes and arrangements of one material were tried. Third, different thicknesses were tested. Corona currents under abnormal conditions may vary randomly by as much as 10% over short periods of time such as 1 minute. The mean value of the current was recorded in an effort to present an order of magnitude. It is doubtful, therefore, whether it is possible intelligently to discuss differences of curves which lie within 10 or 20% of one another. The normal corona currents from clean polished electrodes are reasonably stable for short periods of time, as they usually do not vary by more than 1 or 2% during 1 minute. Another effect occurring in volt-ampere curves is hysteresis. The curves have a tendency to jump from essentially zero to a rather high current on the way up and to fall continuously on the way down. Each curve shows an arrow indicating the manner in which it was taken.

Current-voltage curves for flares produced by insulating material on a positive active electrode are very similar for a wide range of materials. Most of the flares were produced by organic insulation since this was easier to handle. To be sure that the phenomena were not due to organic materials, pieces of glass and quartz tubing were placed on the wire and were found to give the same type of current-voltage curve as the organic insulation. With a negative wire a band of insulating material seems to produce only a comparatively small change in the current-voltage curve.

If there are metallic projections from the active electrode, high local gradients will cause corona to start at lower voltages than normal and abnormally high currents will result; but this is true for both polarities. Therefore, the ring of insulating material seems to be necessary to cause the peculiar phenomenon of high positive currents and almost normal negative currents. In order to check the possibility of sharp edges on the insulating material causing high local gradients, which in turn would cause glows and higher currents, two trials were made as follows. First, vacuum grease was applied in a rather thick film (approximately 1/16 inch) to a 3/4-inch length of 3/16-inch-diameter center electrode, and curves similar to those in Fig. 5 resulted. Then the electrode with vacuum grease was held over a dirty gasoline flame so that a complete film of carbon, which is a good conductor as compared to most

VoL
Pt.
195

insulators, was deposited over the vacuum grease. Volt-ampere curves were then retaken. The positive curve was almost exactly the same as the normal curve from clean electrodes, and the negative curve was about normal also. This same procedure was tried with Scotch electrical tape, with similar results. These results indicate that the insulating film causes conditions different from those of conducting projections on the active electrode, so that, when an insulating film is covered with conducting carbon, the abnormal corona ceases and the currents become normal.

Fig. 9. Volt-ampere characteristics comparing flares caused by different insulating materials

Positive 3/16-inch-diameter center electrode. Friction tape, vacuum grease, and Scotch electrical tape applied to a 3/4-inch length of center electrode. Quartz applied to a 6-inch length of center electrode

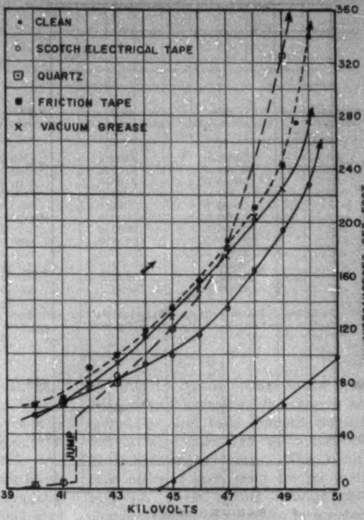

Fig. 6 shows the effect of different sized areas of insulation on the volt-ampere curves of the positive flares. The spirally taped electrode gives the highest currents because flares are established over the complete length of the metering section. The most interesting curves, however, are those in which very small areas of insulation, for example, a 1/32-inch-wide ring of Scotch electrical tape on a 3/16-inch-diameter electrode, causes essentially the same abnormally high currents as do the 3/4-inch-wide rings. The smaller areas of insulation do tend to produce more unstable currents in that there is more variation in current over short periods of time and the curves are not as repeatable as those taken with the 3/4-inch-wide ring of insulation. It is evident from the curves of Fig. 6 that when the area of insulation on the 3/16-inch-diameter active electrode is changed from a 1/32-inch-wide ring to a 3/4-inch-wide ring or to a 3/4-inch-wide half-ring, the voltage–current characteristics remain essentially the same. This fact seems to indicate that the flares are produced at the edges of the layer of insulation. This can be substantiated visually by noting that the stems of the flares always start at the edges of the layer of insulation. Exceptions to this are materials which can break down electrically and form holes; for example, grease and friction tape. The holes can support flares, so that the actual length of edge of the insulation layer is increased by the addition of holes.

The effect of thickness on corona currents from flares is as follows: one layer of tape produces higher currents than do 25 layers. Also, a thicker piece of glass tubing on the center electrode produces less current from flares than does a thinner one. It was found impossible to start flares with thin films of oil or with 50 turns of Scotch electrical tape. Since a zero thickness of insulation and a very large thickness of insulation (about 1/2 inch) will not produce flares, it is implied that there is some optimum thickness. Actually, one layer of Scotch electrical tape about 10 mils thick produces flares more reliably and more readily than do many layers. When grease is applied in varying thicknesses, holes are made due to electrical breakdown, and these holes, which support flares, always seem to occur at thicknesses between 6 to 20 mils. One interesting thing noticed about brass electrodes, however, was that, if they are left for about a month to tarnish in the atmosphere and to pick up dust in a rather dusty room, the electrode will support visual positive flares and will exhibit higher currents and premature sparkover.

Experiments were conducted with plastic wood, which can be shaped on the electrode when wet and then allowed to harden. When wet, the plastic wood can break down electrically and form holes which will support flares; however, when dry, it cannot be broken down, and flares can only form at the edges or at previously formed holes. If wet plastic wood is allowed to produce flares, holes will be formed, and when the plastic wood is dry, flares will be established at these same holes. However, if the holes are tapered with a very small reamer after they were dry, the flares will cease. Fig. 7(A) shows where a flare appears when a layer of high-dielectric-strength insulation is causing it. Fig. 7(B) shows how flares may be initiated and retarded at will by adjusting the shape of the plastic wood on

Table I. Test for Opposite Sign Ions With Flares

the center electrode. (Assume the plastic wood will not break down electrically, as is generally true when it is dry.) In Fig. 7(B) a flare will not start at the top of the plastic wood, because the surface tapers gradually into the electrode. However, at the bottom the flare will start because of the perpendicular surface near the optimum thickness. It is possible to start and stop flares at will by adjusting the shape of the plastic wood as described; however, it seems that the perpendicular surface supporting the flare has to be quite smooth. If the surface is roughened with a knife or drill, flares are reluctant and sometimes impossible to start. Once a flare has been started, however, it is easy to restart it. It may be possible that the active region of glow about the surface tends to smooth off the jagged edges, thereby making it easier to start the next flare. There can be no such control of flares when the insulating layer breaks down electrically, as with, for example, grease and friction tape.

Fig. 8 shows the hysteresis effect of the voltage–current curves of the positive flare. The hysteresis curves are repeatable if sufficient time is allowed after the current goes to zero. In the tests reported here, about 1 or 2 minutes must be allowed at zero current in order to repeat the curve of Fig. 8 over and over. If the time is not taken, the large current jump occurs at a lower voltage, and the shorter the time the lower the voltage until there may appear to be negligible hysteresis. The arrows on the graphs tell the direction in which the voltage was being varied.

A very important characteristic of volt-ampere curves of abnormal active electrode corona is the tendency for premature sparkover or arcing of positive polarity. For a wide range of sizes of the center electrode in the 9-inch-diameter cylinder, if some insulating layer causes a flare, sparkover occurs between 50 and 55 kv. There seems to be little correlation between breakdown voltage and center electrode size. Different insulating materials seem to cause only very slight changes in breakdown voltage. (Fig. 9 gives volt-ampere characteristics comparing flares caused by different insulating materials.) Negative abnormal corona will not cause the excessively premature breakdown that positive flares will. In fact, the breakdown voltage of negative abnormal corona on the 9-inch cylinder was always above 70 kv which was the capacity of the source used. It is interesting to note from Peek's studies[5] that the order of magnitude of sparkover voltage for clean electrodes for a 9-inch-diameter cylindrical geometry is above 100 kv.

Where there is a glow, one suspects that ions are being formed, and that ions of the unwanted sign may interfere with the charging of particles. In order to study this question, precharged balls were dropped through the corona region using the apparatus shown in Fig. 1. The results of a test at 50 kv are shown in Table I. There was a slight indication of ions of the wrong sign at a radius of 1.4 inches, but at radii over 2 inches no evidence of ions of the wrong sign was found. It is possible that there may have been some point on the circumference with a more active glow and a significant number of ions of the wrong sign. However, if such a region exists it was not found in a number of tests and so would not appear to have any large effect on the average charge imparted to particles.

Measurements of the charge imparted to steel balls show that at a given voltage corona from clean electrodes does not give as high a charge as the corona which accompanies flares. Since for larger radii there are no ions of the wrong sign and since the balls are reaching substantially the steady-state charge, it appears reasonable to plot both the charge and corresponding computed field

strength. This is done for a series of tests in the curves of Fig. 10. These curves indicate that flares give a marked reduction in gradient near the wire and thus increase the gradient at larger radii. Since 80% of the charging volume lies outside of a 2-inch radius, the effective charging ability is considerably increased for a given voltage. Of course, from a practical viewpoint this gain is usually nullified by the reduced sparkover voltage which accompanies the flares.

Back-Ionization

Back-ionization is a major trouble in many precipitator applications. Photographs showing the glow on the large or passive electrode and curves of current as a function of voltage have been published in a previous paper.[6] The work described here attempts to study the charging of particles and to determine under what conditions ions of the wrong sign exist in this type of abnormal corona.

Q_N = The net charge remaining after the precharged ball is dropped through the corona being studied.
Q_e = The charge imparted to an initially uncharged ball by dropping through the corona being studied.

In back-ionization with actual dust deposits, it is difficult to obtain reproducible tests. Some tests were made in which the 9-inch cylinder was lined with varnished cambric. The cambric was thick enough so that it would not break down under application of the available voltage to the wire. A large number of pin holes were punched through the cambric before it was cemented to the cylinder. This gave a high-resistivity lining which could form a glow at each of the punched holes. There was some question that the cambric might carbonize at the holes and change the characteristic and some blackening at a few holes could be observed, probably where arcover occurred. However, the "simulated" back-ionization obtained using this perforated varnished cambric gave more reproducible curves than when actual dust layers were tested. These tests simulated the condition of a very thick layer of high-resistivity dust on the large or passive electrode.

When the corona current for clean electrodes is compared to the current with high-resistivity dust on the large electrode as in Fig. 11, there is usually a region at low voltage where the current for the clean electrode is higher than for the condition where the large electrode is covered with high-resistivity dust. At some point the curves cross and above this crossover the current with back-ionization increases much more rapidly than the current with clean electrodes. The high-current condition is explained by the fact that ions of the wrong sign tend to neutralize space charge and in this way increase current. It might seem that a current below normal would have no ions of the wrong sign and that this low-current condition would effectively charge particles.

In order to investigate the possibility of an optimum corona voltage in the presence of back-ionization, the charges acquired by steel balls dropped through corona were measured as a function of radius and voltage. The results of a series of such tests are shown in Fig. 12. These results indicate that charging cannot be improved by a reduction in the voltage. Another interesting feature is the effect of radius on the reduction of charge in the presence of back-ionization. The reduction in charge brought about by back-ionization is much greater near the outer electrode than it is near the inner electrode. This indicates that there is a higher percentage of ions of the wrong sign near the outer electrode.

In order to detect ions of the wrong sign, the precharger was energized to impart a high charge. In this test the precharged balls are dropped through the corona being studied and the resulting or final charge measured. If the charge remaining on the balls is equal to the precharge, then it is assumed that there are no ions of the wrong sign in the corona being studied. On the other hand, a marked decrease in charge indicates that there are ions of the wrong sign.

The results of one series of tests is shown in Table II. For this series a small wire, 0.0063 inch in diameter, was used so that at 40 kv and with clean electrodes the variation of voltage gradient with radius was quite small. With clean electrodes at 40 kv the charge was about 0.65×10^{-9} coulombs per ball over the range of radii that could be measured. The precharge used was from 1.4 to 1.5×10^{-9} coulombs so that it was well above any charge that could be obtained from the corona being studied. At 10 kv the current is only 2.3 microamperes and at this low current there is no

Q_B=charge imparted to steel balls with back-ionization

evidence of ions of the wrong sign; however, the charge acquired by the ball at this low voltage is so small that it is of little value. At 20 kv the current is 28.5 microamperes as compared to 65 microamperes for clean electrodes or 44% of normal, but ions of the wrong sign are present in sufficient numbers to reduce the precharge almost to the charge that would be obtained without precharge. Of course, at any higher voltage there is greater evidence of ions of the wrong sign.

Tests were next made with a thin layer of dust precipitated onto the inside of the passive electrode. The apparatus was enclosed so that it could be heated slightly above room temperature in order to control relative humidity and resistivity. The dust used was fly ash from a station where considerable trouble had been experienced with precipitators. Resistivity was measured with the apparatus described in a previous paper[6] at the same temperature and humidity as was used for the corona measurement. With this thin layer of dust (less than 1/32 inch thick) the current measured with the high-resistivity dust was never significantly lower than that with clean electrodes. With a dust layer at a resistivity of 2.5×10^{11} ohm-centimeters and at 20 kv the current was normal but there was a definite indication of ions of the wrong sign. As the voltage was increased the corona current tended to be above normal and the loss of charge from a precharged ball was greater, indicating an increase in the percentage of ions of the wrong sign. Results obtained by dropping balls at a radius of 3 inches are plotted in the curves of Fig. 13. The upper curves show the current both for clean electrodes and for a thin layer of high-resistivity dust on the outer electrode. The plot of charge acquired by a 3/16-inch sphere with clean electrodes rises steadily as the applied voltage increases. However, with a thin layer of fly ash having a resistivity of 2×10^{11} ohm-centimeters the charges for 10 kv and 15 kv are nearly the same as for clean electrodes. Between 15 and 20 kv the charge acquired by spheres reaches a maximum and in the higher voltage range decreases to a very small value.

The results shown in Fig. 13 indicate that corona current is not necessarily a reliable indication of the charging ability of corona. For example, at 20 kv the current is normal and yet the charge has dropped off appreciably as compared to that for the clean condition. From the results of the test for ions of the wrong sign, curve Q_R of Fig. 13, it appears that at 10 kv a sphere precharged to 14×10^{-10} coulombs lost over 20% of this precharge in dropping through the corona region. This indicates a significant number of ions of the wrong sign even though the effect on the acquired charge is small. At 30 kv about 90% of the precharge is lost in traversing the corona region and the charge acquired by an initially uncharged sphere is less than 20% of that which would be received if the electrodes were clean.

In the series of tests shown in Fig. 14 the voltage was held constant and the radius at which the balls were dropped was varied. With a fine wire as the active electrode the charge acquired was nearly independent of radius if the resistivity of the dust on the outer electrode was low. However, if the temperature was raised so as to reduce the relative humidity and increase the resistivity, the charge acquired was reduced at all radii but the reduction was much greater near the outer electrode. This agrees with the tests simulating the thick dust layers and indicating marked recombination of ions.

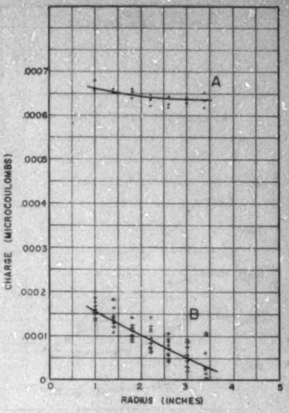

Fig. 14. Charge as a function of radius

0.0063-inch-diameter wire at +40 kv

Thin layer of fly ash on outer electrode

A—High relative humidity

B—Low relative humidity

One outstanding characteristic of the curves of Figs. 12 and 14 is the decrease in charge acquired by a sphere dropped at a large radius as compared to one dropped at a small radius. The curves of Fig. 12 indicate that this characteristic is much more pronounced at high voltages. At a large radius the charge increases very little as the voltage increases. In contrast to this, if the spheres are dropped at a small radius the charge acquired increases much more rapidly as the applied voltage increases. This indicates that at the high-current condition obtained at the higher applied voltage a marked recombination of positive and negative ions is occurring. Near the outer electrode where the positive ions are generated the fraction of positive ions is high and the resulting charge acquired by particles is low. Nearer the wire a large fraction of the positive ions have recombined with negative ions so that there are relatively few ions of the wrong sign and the charge acquired by particles is a relatively large fraction of that which would be acquired if the electrodes were clean.

Discussion of Results

Flares caused by insulating materials on the positive active electrode result in a large increase in current in the region near the voltage at which corona starts. High-resistivity material on the passive electrode with both polarities may show a distinct decrease in current in this low-voltage range but a current which may be several times normal at higher voltages. Probably the most important characteristic of flares is the marked reduction in flashover voltage. At a given voltage the charge imparted to particles may be increased by flares but this is of no practical value because of increased ozone generation in the air-conditioning application and reduced sparkover voltage in industrial dust-collecting applications.

The tests reported here describe only some of the characteristics of flares. The flares appear to cause such a marked reduction in flashover voltage that it would be desirable to know more of the mechanism involved. It seems possible that this mechanism may be responsible for flashover at relatively low voltage in other types of equipment.

The tests with high-resistivity dust indicate that corona current is not a reliable indication of the ability of the corona to charge particles. Even in a short length of one wire the current can be normal and yet have a high percentage of ions of the wrong sign, which results in poor charging. In a larger unit one section of wire may have a high current and another a low current, which produces a normal total current but very poor charging. In a single-stage precipitator the rate of precipitation depends upon the charge on particles near the outer electrode. Tests show this charge can approach zero with bad back-ionization.

High-Efficiency Push-Pull Magnetic Amplifiers with Transistors as Switched Rectifiers

A. G. MILNES
MEMBER AIEE

IN MANY magnetic amplifiers, push-pull action is used to obtain outputs that depend in polarity (or phase) on the signal polarity (or phase).[1,2,3]

If polarity-reversing d-c output is required, series or T-summing circuits may be used, but considerable power is lost in such networks and the theoretical efficiency has a maximum value of 17%. Improvement is possible if the load has twin windings, since then magnetic summing may be adopted. The effective use of the load winding space is halved by the need for two load windings, only one of which is energized in the full output condition, and therefore the efficiency of magnetic summing is not more than 50%. For d-c loads where twin load windings are not practical, a bridge configuration has been described that requires twin windings on each core of the amplifier.[1,4,5] A dummy load is necessary for reset and ballast purposes and this reduces the circuit efficiency to 50% or less. In motor-type applications there are difficulties in matching the dummy load to the machine load under varying speed conditions, and a compromise must be made that involves additional sacrifice of efficiency.[4]

In this paper, various circuits are considered that use transistors as switched rectifiers and efficiencies well in excess of 50% for ± polarity-reversing d-c outputs are obtained. Alternating-current output circuits are not examined, since in general these do not incur the efficiency losses of d-c output circuits. The circuits on which the work is based are the push-pull voltage-reset (Ramey) amplifiers proposed by Maine, in which the circuit elements are coupled by switched rectifiers that prevent circulating currents from bypassing the load.[6] A typical full-wave push-pull circuit is shown in Fig. 1(A) and this has input/output characteristics as in Figs. 1(B) and 1(C). With a d-c signal of one polarity, cores *1* and *4* provide output in sucessive half-cycles while cores *2* and *3* are "passive"; and for the other signal polarity the action interchanges and cores *2* and *3* provide output of reversed polarity. With an a-c signal, cores *1* and *2* provide a-c output and *3* and *4* are passive; and reversal of the signal phase brings about reversal of the core actions and the phase of the a-c output reverses. The switched rectifiers *a*, *b*, *c*, *d* in the load side are controlled by bias voltages of gate-supply magnitude acting through resistors R_z equal to the load resistance. This ensures rectifier cutoff for half of each cycle and limits the rectifier current flow to the load current magnitude. With these necessary proportions the switching power for the load circuit is twice the maximum load power, and hence the maximum circuit efficiency is 33% (assuming the power loss in the control side of the circuit to be small).

The concept that suggests itself for the improvement of efficiency in this circuit is the substitution of transistors for the switched rectifiers since the functions of half-cycle cutoff and current limiting can then be performed for the expenditure of much reduced power.

Push-Pull Reset Circuits with Transistor Switches

In switched operation of a transistor the base-drive current need be only equal to the output current divided by the current gain of the unit, which is normally 10 or more. The base-drive voltage must be sufficient to supply this base current in a typical switching configuration and this is perhaps merely 2 or 3 volts. Thus the base-drive power may be only a few per cent of the power controlled as a switch.[7] The voltage drop between emitter and collector when acting as a closed switch

B—With transistors in both the control and the load sides

may be 0.3–1.0 volt at full-load current depending on the transistor type and the amount of drive provided. The total switch loss therefore is unlikely to exceed 5% of the power switched in a correctly proportioned circuit.

Rectifiers *a*, *b*, *c*, and *d* of Fig. 1(A) may be replaced by transistor switches as shown in Fig. 2(A). Then for 5% switch loss per pair of transistors the theoretical maximum efficiency of Fig. 2(A) should be about 90% as compared with 33% for the earlier circuit. Other losses that must be allowed for include winding resistance losses and normal rectifier forward-voltage losses, and these may amount to 10 to 20% depending on the design proportions. The power supplied to the control circuit for flux reset is normally small, but also may be allowed for in assessing efficiency.

The circuit of Fig. 2(A) may be rearranged to use *p-n-p* and *n-p-n* units in complementary symmetry, Fig. 2(B), which allows base drive to be obtained from the gate-voltage windings, thus simplifying the supply transformers. In Fig. 2(B) transistor switches are shown also in the control side of the circuit, although the power levels there are low and the effect on efficiency correspondingly small.

The circuit of Fig. 2(A) gives reversing-polarity d-c output for a d-c signal and reversing-phase a-c output for an a-c signal input. Rearrangement of the control circuit as shown in Fig. 3 interchanges the control action so that a d-c signal gives a-c output and vice versa. Although only full-wave circuits are given, the same principles apply to half-wave versions of these circuits.[6]

Since the circuits are constructed from voltage-reset-(Ramey-) type configurations the transient response to be expected is merely the half-cycle delay of such arrangements.

The switch-off condition for a *p-n-p* transistor is that the base must be positive with respect to both of the other electrodes. Thus the magnitude of the switch-off voltage between the emitter and the base limits the voltage that can be sustained with the collector positive with respect to the emitter.[7] This is the reason for the inclusion of diode rectifiers in series with each transistor, and the possibility exists of eliminating the diodes if the base-switching voltage can be made large.

Experimental Examination of the New Push-Pull Reset Circuits

An experimental examination was made to establish that the full-wave circuits of Fig. 2 and Fig. 3 functioned as expected and gave high efficiency. Four cores of Orthonol of $2^1/_4$-inch inner diameter, $3^1/_2$-inch outer diameter, and 3/4-inch tape width were provided with gate windings of 500 turns and control windings of 166 turns. At 60 cycles per second the gate-winding-saturation voltage per core was just over 50 volts (rms). In these push-pull circuits, triggering of an active core produces voltage across the load which adds to the gate-voltage supply of the passive section of the amplifier and therefore the gate-voltage rating in push-pull must be half that for normal single-ended operation. In these experiments the gate voltage of each half of the circuit was therefore set at 25 volts. The power transistors available were *2N68* units, and these were selected to have collector-emitter turnover voltages in excess of 60 volts when the base was positive with respect to the emitter. For the circuit of

B—Action with a-c signal
C—Action with d-c signal

Fig. 2(B), *n-p-n* transistors are also required and type *2N95* units were used.

Examination of the circuit waveforms confirmed the expected action and the improvement in efficiency. A typical characteristic for the circuit of Fig. 3 for a load resistance of 150 ohms and gate and reset voltages of 25 and 9 volts, respectively, is given in Fig. 4. The circuit efficiency depends on the output level and increases as this approaches full output. At a signal level of 9 volts, corresponding to almost full output in Fig. 4, the efficiency represented by the load-power output divided by the input power was 80%. The need for high-impedance wattmeters to measure true power may be avoided by taking other ratios, such as that of the load current to the total input current, to represent the effectiveness of the push-pull arrangement. For the characteristic of Fig. 4 a load current of 124 milliamperes required an input current to the gate side of 144 milliamperes (mean) and an equivalent of 25 milliamperes to the control circuit side. The ratio of load to input current was therefore 0.76 and the ratio of output–input volt-amperes was 60%. This represents a considerable improvement over values of less than 17% for conventional circuits and the values of less than 33% for switched rectifier circuits.

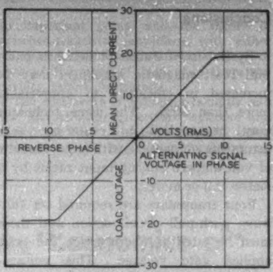

Fig. 4. Typical experimental output characteristic for the circuit arrangement of Fig. 3

For these experiments the amplifier elements were designed to be of negligible winding resistance to facilitate efficiency studies; the number of turns was low and the input impedance was correspondingly low (about 700 ohms). This had the effect of limiting the power gain in the experiments; with a load of 150 ohms the gain was about 20 and for a 50-ohm load the gain was about 60. In any practical application the gain could be improved by redesign of the core elements.

Push-Pull Center-Tap Self-Saturating Circuit of High Efficiency

The voltage-reset (Ramey) amplifiers that have been examined in the high-efficiency push-pull configurations have minimum output for zero signal. Conventional self-saturating amplifier circuits do not have this type of characteristic, although by added bias the output at zero signal may be reduced to a low value. The advantage of this condition is that for any given direction of signal two cores of the push-pull configuration do not contribute to the output and therefore the fluxes do not saturate and thereby open up circuit paths through which circulating current may bypass the load. With this consideration in mind it was decided to examine the transistor technique of push-pull coupling with conventional self-saturating circuits suitably biased to be of low standing current at zero control signal current.

The circuit arrangement examined, Fig. 5(A), is identical on the load side to the configurations (Fig. 2(A) and 3) already discussed. On the control side the bias and signal circuit connections are such that cores *1* and *4* may be regarded as forming a center tap self-saturating circuit acting in push-pull with a similar configuration formed by cores *2* and *3*. In Fig. 5(B) the full-line curve is a typical push-pull characteristic and the dotted line represents the output obtained from cores *1* and *4*, with the other cores disconnected to show the extent of the bias provided. The gate voltage was 25 volts and loads in the range of 150 to 50 ohms were used. For a load current of 290 milliamperes in 50 ohms the total input current to the circuit was 325 milliamperes (mean). This represents a volt-ampere output/input ratio of 0.52, which is very much better than for conventional series or T-summing networks.

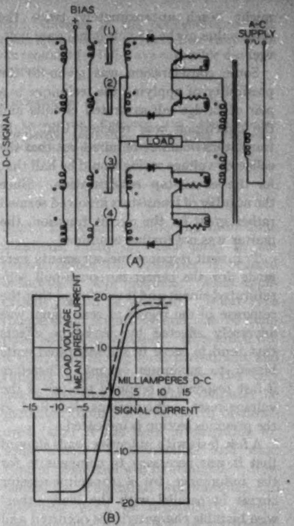

Fig. 5. Push-pull self-saturating amplifier with switched transistors

A—Circuit of push-pull center-tap amplifier
B—Experimental output characteristics

With Orthonol cores, there was a tendency for looping of the characteristic to occur at low signal levels. Triggering is a well-known effect in this class of core material, but to confirm that the circuits were not responsible the experiments were repeated with *4-79* Mo-permalloy cores and the effect was absent. Inspection of the waveforms for both types of material showed that the reverse voltages across rectifiers and transistors might reach approximately twice the peak value of the 25-volt (rms) gate voltage.

Some consideration was given to the possibility of applying the technique to a pair of bridge self-saturated circuits and the conclusion was reached that eight transistors would be required but that the collector voltage rating would be half that for the center-tap configuration. Since the number of transistors involved seemed rather great for the circuit function, the matter was not further examined.

Transient response measurements were made for the center-tap push-pull self-saturated circuit and it was found that the response in the region of zero signal was adversely affected by dead-time effects that tend to occur in self-saturated units biased to minimum output. Therefore if fast response is required the use of the voltage-reset configurations described in the previous section is indicated.

A few tests with inductive loads showed that it was necessary to compensate for the inductance by a capacitor-resistor circuit in parallel with the load, otherwise bistable characteristics occurred and circulating currents could flow between the push-pull units.

Conclusions

By the use of transistor switches, push-pull reset magnetic amplifiers may be increased in efficiency to appreciably more than 50%. The same technique may be applied to center-tap self-saturating connections with improvements of volt-ampere output/input ratios by a factor of 3 or more.

Four transistors are required for full-wave push-pull circuit action and these must be rated at about twice the peak applied gate voltage. This voltage-rating requirement constitutes at present a limitation on the applicability of the technique. The power dissipation in the transistors is small and temperature effects on linear parameters are not important since switched action is used.

In many magnetic amplifier applications the low volt-ampere efficiency of conventional push-pull configurations is not important. In certain military applications, however, the power supply available is limited and excess current demand must be avoided to conserve power and to restrict unnecessary heat generation that may present dissipation problems. With a limited power supply the source impedance is usually appreciable and excess current demand may cause deterioration of supply-voltage waveform and therefore adverse coupling interaction between independent circuits operating from the same source. In such circumstances the high-efficiency push-pull magnetic amplifier circuits proposed may well be found of value.

Discussion

N. L. Schmitz and **T. Bernstein** (University of Wisconsin, Madison, Wis.): Dr. Milnes' combination of gate windings and either switched transistors or rectifiers as evolved in this paper appears to have many of the advantages and few of the disadvantages of the rotating machine as a multiple-input reversible-polarity power amplifier for resistive loads. Among the disadvantages of the scheme is the duplication of control elements, namely, switched transistors in series with the gate windings of a magnetic amplifier in the load circuit.

We believe that this disadvantage is avoided with consequent reduction in physical size of the magnetic amplifiers and copper losses through the use of the circuit shown in Fig. 6. In this circuit the transistors are switched at adjustable rather than fixed firing angles by means of low-power control-circuit magnetic amplifiers. In comparing the power elements in the load circuit of Figs. 2(A), 2(B), and 3(A) of the paper with those in the load circuit of Fig. 6, it is seen that the proposed circuit replaces four transistors, four rectifiers, and four gate windings with four rectifiers and two transistors. The control circuitry is of comparable complexity in both cases. Windings *1*, *2*, *3*, and *4* are gate windings of a typical magnetic amplifier circuit rated for relatively low power service as a source of base-drive current. Bias and control windings (not shown) comparable to those shown in the paper (but on a relatively smaller size core) control the phase angle of core saturation and consequently switching angles of the two transistors.

Magnetic amplifiers have been found to be well suited to the control of transistor switching angles in single-ended nonreversible d-c power amplifiers. Preliminary studies indicate that reversible-polarity power amplification can be obtained in this manner. This scheme of operation appears to offer no greater inherent difficulty as to circulating current, loss of bias, and drift than appears in other schemes which have come to our attention thus far.

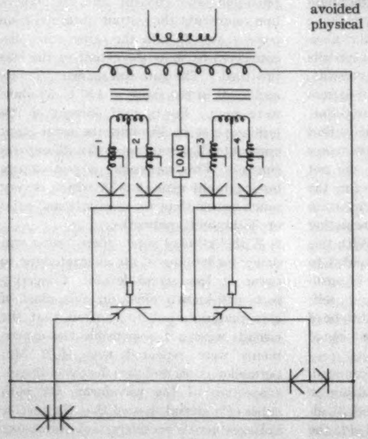

Fig. 6. Reversible-polarity d-c magnetic amplifier using transistors with variable switching angle

A. G. Milnes: The present trend from magnetic amplifier to switched transistor configurations is proceeding rapidly, and the circuits in the paper represent only a transition stage in the process. It might be said in favor of the series arrangement of reactors and transistors that transistor switching (if the load is effectively resistive) occurs at low currents, thus eliminating high peak-dissipation powers. However, in view of the success of switched-transistor d-c to a-c converter circuits this does not seem an important point, and the future of switched-transistor amplifiers, with either magnetic-amplifier-modulated drive or phase-shift control of drive as in thyratron circuits, seems promising.[1]

The comments of Professor Schmitz and Mr. Bernstein are therefore welcome and the circuit they show is particularly interesting since only two power transistors are used, whereas in the configurations that come more readily to mind four transistors are required for full-wave reversible d-c-type outputs.

The Practice and the Economics of Applying Digital Computers to Engineering Problems

P. A. ABETTI
MEMBER AIEE

S. B. WILLIAMS
ASSOCIATE MEMBER AIEE

THE TRULY EXPLOSIVE progress achieved by the digital computer in the last 10 years, and its outstanding contributions to the solution of scientific, engineering, and data-processing problems have been recently reviewed by Harder.[1] There is no evidence that this phenomenal rate of progress will diminish in the next 10 years.

The practical application of digital computers to engineering problems has grown in parallel to the advances in the computer art. Thus the number, size, and cost of computer installations have also grown phenomenally in the last 10 years. For the General Electric Company, which makes extensive use of computers, the last published figures[2] of actual or planned medium-sized and large-sized installations are given in Table I. The great majority of these installations is used, either full time or part time, for the solution of engineering problems. It may be estimated that at present there are about 150 large-sized computer installations in the world, and about 1,000 medium-sized installations, and probably as many more being installed, planned, investigated, or considered. The economic significance of this may be assessed by realizing that the budget of a medium-sized installation may be anywhere between $100,000 to $200,000 per year, and the budget for a large-sized installation anywhere between $500,000 and $1,000,000 or more per year.

Because the art of applying digital computers to engineeeing is still in its infancy and because of the continuous rapid advances in computer hardware and programming techniques, it has been difficult to "think through" thoroughly many practical and economic aspects of planning, organizing, operating, and measuring a computer installation. Many installations, and by no means the least successful ones, have been developed more from faith than from reasoned plans supported by adequate technical or economic justifications. Others have been achieved after lengthy and detailed procedural and economic studies but in several cases, particularly in the area of application to data processing,[3] the results to date have been disappointing.

At present, there exists no established philosophy (understood as "the body of principles underlying a given branch of learning or major discipline") for the application of digital computers to engineering and data-processing work. A first attempt to establish such a philosophy for the relatively narrow field of design of electric apparatus has been made by the authors in a companion paper.[4]

Practical Questions

A philosophy is perhaps less urgent and important than a multitude of practical questions which arise continually in the mind of all groups contemplating a new computer installation, and often of groups who already have one in operation. There are specific and immediate questions, many of which must be answered before the computer is ordered or installed. For instance: What applications should be selected? What type (business or scientific) and size of computer should be selected? How much will it cost, considering both investment and running expenses? How can the economic contribution of the computer be predicted (before it is installed) or measured (after it has been in operation for some time)? What number and what type of personnel will be required? How should the procedural, programming, and operating work be organized? Should the computer installation be centralized or decentralized; should it be operated as an "open shop" or a "closed shop"? How should the communications be organized between the engineering group and the computer? What will be the effect on product quality and delivery schedules? What will be the effect on the total number of technical and nontechnical personnel? What will be the effect on the training, morale, and required abilities of this personnel? . . . and so on.

All these questions are legitimately pertinent, actual and, in many ways, controversial. It must be realized that, as the discussion becomes more concerned with specific and detailed issues, the answers are less generally applicable than a broad philosophy and must be based on the specific characteristics and circumstances of the individual application considered. Nonetheless, after these words of caution, the authors will try to answer the foregoing questions to the best of their knowledge, as based on their experience in using various types of IBM (International Business Machines

Table I. Number of Digital Computers in the General Electric Company

Type	Installed	On Order	Total
Medium-sized: *IBM 656*, Datatron, etc.	20	26	46
Large-sized: Univac, *IBM 704, 765*, etc.	8	6	14
Total	28	32	60

Paper 58-162, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Operations Department for presentation at the AIEE Winter General Meeting, New York, N. Y., February 2–7, 1958. Manuscript submitted October 16, 1957; made available for printing November 12, 1957.

P. A. Abetti and S. B. Williams are with the General Electric Company, Pittsfield, Mass.

Corporation) computers since 1950: small, IBM *604* and the CPC (card-programmed calculator); medium, IBM *650;* and large, IBM *705*, for a great variety and number of problems. The authors' experience has been mainly in the application of computers to problems in research, development, design and engineering data processing arising from power transformers and related apparatus. However, they have followed closely the work of many of their associates in the General Electric Company in other engineering fields, and have carefully studied, through the literature or by means of personal contacts, the work done in other installations, both in this country and abroad. Therefore the following discussion will be restricted to the application of computers to engineering problems (as contrasted to strictly mathematical or to strictly data-processing problems, such as payroll), although probably some of the answers may be applicable to a broader field. Wherever possible, the authors will indicate the order of magnitude of the quantities being discussed and give examples of actual solutions to the questions posed, as drawn from their own personal experience.

Selection and Conversion

Selection of Applications

The first questions encountered in the application of digital computers to engineering problems involve: 1. the selection of specific problems to be solved, and 2. the selection of the size and type of computer. Only after these two initial decisions have been made is it possible to study the economics of the application and to make the final decision as to whether the use of the computer is technically possible and economically justified. Of course, in many cases, there may not be such wide freedom of selection. For instance, a particularly tough problem may become the bottleneck of an entire operation and must be attacked first, or the competitive situation may dictate priority of application to a certain product line in order to improve deliveries, reduce costs, or simply to "keep up with the Joneses," who already are using a computer. Also, a computer might already be available part time in the plant, for instance, in the financial section, and the cost and risk is usually less in utilizing this available computer than in acquiring another for the contemplated applications.

In general, the engineering applications to be preferred are those with high repetitiousness as a whole or in the individual portions of the programs and for which the computational and/or data-processing content is considerable. In all cases, since stored-program computers work anywhere between 100 to 10,000 times faster than the human mind, there must be sufficient volume to keep the machine busy, unless additional uses can be found for it (for instance, in the fields of accounting, payroll, inventory control, etc.), or it may be shared with other components. The requirement of high repetitiousness is dictated by the fact that, at present, programming is laborious, expensive, and time-consuming and becomes the bottleneck in most installations. Programs represent always a high investment in dollars and hard-to-get technical manpower, and only highly repetitive use of these programs ensures an adequate rate of return of this investment.

A method for evaluating the economics of a particular application will be discussed later. At present, it should be noted that in many cases it may not be advantageous to consider each application individually. This is because many applications may have certain portions of the programs in common (for instance, mathematical and editing subroutines) so that they may share jointly the total cost. Thus, many applications which would appear too expensive individually may be justified if considered jointly. Furthermore, it is very seldom in modern industry that an individual application has no relationship to the others. In many cases, the highest returns are obtained by integrating the various related applications into one single program so that the total will be larger than the sum of its parts. A typical example is the integration of design of electric apparatus with cost estimating, previously considered to be entirely separate functions, one pertaining to engineering and the other to finance. The program developed by the authors and their associates for preliminary design on the IBM *705* of power transformers (rated from 5,000 to 500,000 kva, any voltage, 2- and 3-winding) requires 90 seconds to run in total compared to the 2 weeks necessary to do the job by hand. Of this time about 70 seconds are for the engineering portion and 20 for the cost-estimating portion. It is estimated that two or three times longer running time (at several hundred dollars per hour) would be required for doing the same job with two separate programs, each with its own output and input. Thus, in selecting the applications, particularly when a large computer is being considered, it is best to consider a broad class, such as a product line (distribution or power transformers, induction motors, generators, etc.) or the major problems in a given branch of science or engineering (field problems, thermal calculations, stress analysis, etc.) rather than a multitude of isolated applications. The last case is more typical of a commercial computer service organization which usually takes whatever is offered to it by its clients and treats each problem individually.

Selection of Computer

The selection of the type and size of the computer depends on the nature of the application considered, the volume expected, and whether it will be used exclusively for engineering or for other applications also. Even if the contemplated use is exclusively for engineering, the type of application may vary considerably and influence the choice. On the one side there are the purely mathematical problems which involve a tremendous number of computations, practically no logical decisions, no data processing, a relatively small amount of input and output. Typical examples of this type of problem are the solution of a system of simultaneous linear equations, statistical multivariate correlation analyses, and the calculation of transformer reactance by the circular field method.[4]

On the other side are the engineering data-processing problems, which are encountered quite frequently in the design of electric apparatus.[3] In such problems the number of computational instructions (such as add, subtract, divide, multiply) may be 30% or less of the total. The remainder are logical decisions, reading and writing, comparing, etc., since a large portion of the design process, particularly of a standardized product, entails the reading, sorting, and selecting of already available information rather than the creation and computation of new information. In this last case, "business-type" computers with variable word lengths, high speed of logical decisions and output-input, and relatively lower calculation speed have certain advantages over the scientific, fixed-word-length, computers. For instance, in most design work, slide rule accuracy has been traditionally sufficient, and the order of magnitude of the variables involved is well known (for instance, dimensions of the components, losses per unit weight, temperature rises, etc.); thus there is no need to carry 10- or 12-decimal digits in all the computations or to use the floating decimal system. For this reason a special 5-digit "slide-rule" system was developed[6] for the Pittsfield, Mass., card-programmed calculator in 1954, in addition to the 10-digit system previously developed in Schenectady for mathematical work. This new system effectively doubled the capacity and the speed of the CPC, a small and extremely slow computer by modern standards, and allowed the performance on it of the preliminary design of the most complicated types of power transformers, such as extra-high-voltage autotransformers with three windings and 5-legged cores. Since ultimately the memory capacity, speed, and cost of computers depends upon the number of digits carried and the number of operations, there are certain advantages in using no more digits and no more operations than necessary for a specific application.

In any case a stored-program computer with the possibility of performing an unlimited number of loops, is at present required for the great majority of engineering problems. Magnetic tapes become a necessity whenever the amount of engineering data processing becomes considerable, and when it is desired to do a complete design job, not just its computations.[3]

With respect to size, there has been considerable controversy between the advocates of one general-purpose large-sized computer and the advocates of several more specialized small or medium-sized computers. In practice, both solutions are used and are operating satisfactorily, as may be seen by the figures given in Table I for the General Electric Company. Harder[1] shows very clearly that the larger the machine, the lower the cost per computation. For instance, a job costing $300 on a desk calculator would cost $1.00 on a medium-power digital computer and $0.03 on a high-power digital computer. Similarly, the time required would be 2 weeks with the desk calculator, a few minutes on the medium computer, a few tenths of a second in the large computer. In practice, as will be seen, the story is not quite as simple. Here it will be sufficient to mention that the initial investment (as contrasted to the running costs just given) is greater for the larger machines, though not proportionally to their speed. Furthermore, the ratios in speed and cost in the preparation of the input, and in some cases its introduction in the computer and the extraction of results, vary much less than the corresponding ratios just given. Nonetheless, the general statement is valid that the larger machines are more economical, provided there is enough work to keep them busy.

Another very important point, usually neglected by the advocates of several small computers, is that certain applications cannot be accomplished (economically or from any other standpoint) on the smaller machines. A simple illustration is the problem of delivering freight: if individual consignments are small, several station wagons may be better than a truck. But if some are larger than the capacity of a station wagon, it is absolutely necessary to have a truck. Thus a large computer permits applications which could not even be considered on a smaller machine, and spurs engineers to attack the toughest, most complicated and extensive problems, which are the most rewarding technically and economically and the solutions of which contribute the most to the progress of scientific and technical knowledge.

In practice, the choice of the size of the computer may be determined, at least in part, by other than strictly economical and technical considerations. For instance, if a company is decentralized in various autonomous departments, the natural tendency is for each department to want its own computer, for reasons of control, accessibility, prestige, etc. Thus the choice will be several medium-sized computers (unless a department can justify or afford a large one) rather than the joint use of one large machine in a central location. Of course, sooner or later, consideration of the economics and capacity already discussed dictates the minimum size possible. In many cases it would be absurd for each engineering unit to have its small machine, rather than one medium-sized machine for the entire engineering section. The ultimate of decentralization would be for each engineer to have his own computer, and this would mean a return to the time-honored slide-rule! However, as the progress in the computer art continues and the cost goes down, the programming becomes simpler, the trend toward smaller and less expensive machines will become more marked in many engineering organizations.

CONVERSION FROM ONE COMPUTER TO ANOTHER

Since the computer field is progressing at such a fast rate, the choice of the computer must be visualized as a dynamic rather than as a static problem. Thus the problem of selection is similar to that of shooting at a moving target. Since it takes from 1 to 2 years to plan, program, and install a medium or large machine (taking into account present delivery rates) and since the average span of a "computer generation" is of the order of 2 years, it often happens that by the time the chosen model is installed, a newer model is already on the market. Furthermore, the general experience has been that the chosen computer is loaded to capacity in a short time and a bigger and faster one is soon required to take care of the additional proposed applications. For all these reasons, the more general practice is to rent rather than to buy a computer, so that it may be easily exchanged for a larger one as soon as desirable.

The authors' experience in this respect is quite significant. In January 1953, in Schenectady they started using, part time, the CPC, which was the first commerical machine to become available. Compared to modern computers, the CPC appears completely outdated and woefully inadequate. Nonetheless, its many contributions to electrical engineering have been extremely useful. It has rendered invaluable service in introducing many engineers to automatic digital computers (as contrasted to conventional accounting machines), and as the stepping-stone to the modern high-speed, large-storage computers, either with rotating drum storage, such as the IBM *650*, or with magnetic cores and magnetic tapes such as the giants IBM *704* and IBM *705*. The experience with the Schenectady CPC was excellent, and the first power transformer was designed with it in May 1953.[6] Soon it was necessary to order a CPC exclusively for power transformer design, to be located in Pittsfield. This machine (Fig. 1) was installed in February 1954, and it was loaded to a full first shift within a month. The load increased continuously until the machine was used up to 70 hours a week. Bigger and better computers were either available, or had been announced by the manufacturers. The authors and their associates programmed some problems for the *650*, which became available in Schenectady early in 1954. While the *650* yielded very valuable results, it did not appear sufficient for the extensive scientific, design- and data-processing computations which were required in the power transformer department. At this point (May 1955) it was decided to "leap-frog" from the CPC to the *705*, omitting the intermediate step of the *650* or similar drum computers. This decision proved correct and, after 1$^1/_2$ years of extensive planning and programming work, the *705* was delivered in Pittsfield in January 1957; see Fig. 2. It was loaded up

Fig. 1. IBM card-programmed calculator, installed in Pittsfield in February 1954, and removed in June 1957

Fig. 2. IBM 705 electronic-data processing machine installed in Pittsfield in January 1957

rapidly to a full shift and it is now being used extensively for all types of computations.

One of the difficulties encountered in the frequent changeover from one computer to a bigger and better one is the rapid obsolescence of the programs, which represent an extremely heavy investment in skill, effort, and man-years of work. This obsolescence has two aspects, one obvious and one less obvious but no less important. The first is the inescapable fact that the "languages" of the CPC, the *650* and the *705* are entirely different so that the programs painstakingly prepared for one machine are completely useless for the others. The less obvious aspect is that, even if the three machines could all "talk the same language," the programs written for the smaller machines would not make efficient use of the speed and capabilities of the larger machines. In other words, it is necessary to "custom-fit" the program to the particular computer used, in order to obtain optimum utilization. This is necessary, considering that practically all computers are very expensive and are overloaded all the time, and that the economic margin between computers, accounting machines, and hand methods may be small for certain applications, particularly in the data-processing field. The discussers have found what is believed to be a workable and novel solution for this embarrassing problem. The most important and frequent applications have been reprogrammed *ex novo* in *705* language. For the less frequent applications, an automatic programming method has been devised wherein the *705* uses the same input, programs and output as the CPC, and in fact acts as a glorified CPC, but 10 to 25 times faster.[7] The ratio between bona fide *705* programs and CPC is betweeen 60 or 80 to 1, so that considerable speed is being sacrificed by this artifice. However, approximately 25 man-years of programming and "debugging" were saved in this manner, and thus this expedient is definitely economically justified for the less important applications. Having thus made the CPC completely obsolete, it was returned on June 1, 1957. When a conversion system is not available, there is a tendency to retain the older, less effective computers, and this is generally uneconomical and contrary to the natural tendency of the engineer, which is to use always the most advanced techniques available.

Organization

PROGRAMMING AND OPERATION

Before discussing the organizational and economic aspects of a computer installation, the various steps involved in actually carrying out the application of a given important engineering problem on a computer will be described. This step-by-step process is described for a large or medium sized machine with magnetic tapes, which are almost indispensable for any extensive amount of engineering data-processing work. For less important problems, or for a small computer without tapes, the process may be less formalized, and some steps may be omitted but, in any case, the description is still generally valid. First, one must distinguish between two distinct phases of the problem 1. preparing the program, and 2. running the problem on the computer whenever required for production (as contrasted to "debugging"). These are, conceptually and practically, two different kinds of work, and in many cases may actually correspond to different organizational components.

Preparing the Program

1. Meetings are held between the engineers interested in the particular application and people assigned to the computer to define the problem, establish the objectives, and generally discuss the method to be followed. These preliminary discussions may require days, weeks, or months, especially for design synthesis applications.[3]

2. Engineering procedures and programming specialists analyze the problem and prepare flow charts (or block diagrams) showing the flow of information, the logical decisions, and the computations to be made, etc. This is the first step in formulating the program, which is a series of computer instructions. Flow charts may include any number from a few to several thousand blocks.

3. Programmers and coders code the flow chart, i.e., they translate the instructions into computer language. Engineering programs may have any number between several hundred to 100,000 separate computer instructions.

4. The coded instructions sheets are keypunched into program decks of punched cards. These may include any number of cards from a few to several thousand.

5. The program is assembled into its final form by the machine itself and then is tested or debugged by the programmers, who run test cases on the machine and correct errors as they appear. This process may take from 1 to 100 machine hours, and from a few days to months of elapsed time. One hour of machine time is required to debug several hundred program instructions, the number depending on the complexity of the program and in the ability of the programmer.

6. Forms for input data are prepared.

7. The input and output of the test runs is reviewed with the interested engineers, and further corrections and refinements are made.

8. The final checked program is transferred from cards to magnetic tape and is now ready for the production runs. One or more tapes may be required, depending upon the application.

9. The programs are modified and updated as the need arises, upon suggestions of either the engineering group or the computer group.

In practice, many of these steps merge into each other and they may be repeated several times. Also, there is a continuous feedback from one step to the preceding one. In checking out a program it is necessary to ascertain that: 1. the instructions are valid with respect to the particular machine code being used; this is relatively simple, and most errors are of a trivial nature, and 2. the program, logically and computationally, achieves the desired objectives for all possible variations to be encountered in practice. This stage is quite difficult, and requires a thorough knowledge of the problem and the computation process, as well as continuous feedback from the interested engineers and managers.

Running a Job for Production

1. The engineer assigned to a job fills in the input forms according to the specifications and any other special requirements. One or more sheets may be required.
2. These forms are key-punched by the computer operations group onto punched cards. The number of cards may vary from 2 to 10 or 20.
3. Input data cards are sorted and checked on auxiliary equipment for possible errors.
4. If there are many jobs and many cards, these cards may be transferred to magnetic tape by auxiliary card-to-tape operation, to save running time.
5. Following the program instructions, the computer takes the input data, performs the required calculations, and prints the output directly, or writes it on magnetic tape, if it comprises several sheets.
6. By auxiliary tape-to-printer operation, the output is printed out on the standard forms.
7. The output is transmitted to the engineer responsible for the problem. In case of error, e.g., incorrect input data, the machine "hangs up" and he is told what should be corrected.

This running procedure may appear quite detailed but it is designed to save as much as possible of the computer time, which is worth from less than a hundred to several hundred dollars per hour. It should be realized that jobs which would take weeks by hand require only a few minutes on the computer. Therefore the elapsed time between submission of the input data sheets to the computer group and the transmission of the results to the engineering group may involve only a few hours whenever the procedure and the required communications are properly organized. For instance, the Pittsfield *705* is reserved according to a planned regular schedule, for processing, every working day, daily design requirements such as propositions, requisitions, and special studies. If the input data sheets are given to the computer operations component early in the morning or early in the afternoon, the results will be returned to the design office before the end of the morning or of the afternoon respectively. Thus, the total elapsed time is less than 4 hours, corresponding to weeks of work by hand. Other less urgent engineering requirements, including debugging of new programs, are taken care of daily as time is available, with a less rigorous schedule.

ORGANIZATIONAL PATTERNS

The foregoing description of how a design application is programmed and run repeatedly on a computer leads to a discussion of organizational questions. There is at present a great variety of organizational forms, depending upon the size and type of computer, the type and frequency of applications, the time the computer has been in use, and the company's organizational philosophy. In the following paragraphs are presented the authors' ideas on this subject, and how they have been embodied in practice in the Pittsfield *705* installation.

In the preceding discussion three different groups have been recognized: 1. the engineers, charged with the responsibility of obtaining solutions to various problems, either by hand or by computer; 2. the programming group, responsible for preparing correct and economic programs for the selected applications; and 3. the computer operations group, responsible for running the requested individual jobs on the computer correctly, efficiently, and on schedule. In several practical cases, particularly in the smaller computer organizations, or in the initial stage, these three groups may merge into each other and the same persons may be charged with more than one of the responsibilities listed. Nonetheless, it is important to recognize that there are three different kinds of work, at least conceptually. As soon as the computer is loaded up it becomes necessary to identify and split off from their group one or more persons responsible for actually running the machine, allocating time, key-punching the input, etc. This is the nucleus of the computer operations group, which may comprise any number from 1 to 10 or more persons. If the computer is not in the engineering component, e.g., if it is in the financial component, this identification of the operations group is obvious.

The separation between engineering and programming work may be less apparent and less immediate. In fact, there are two schools of thought concerning engineering and scientific applications of computers. In the "open shop" all interested engineers are given programming courses and, in some cases, even courses in operating the machine. The engineers are then free to prepare their own programs, debug them, and run them for production as they see fit and whenever there is machine time available. In the "closed shop" all programming is done exclusively by "professional" programmers in a separate component and they alone are allowed to prepare and debug programs. Thus the engineers have no direct contact with the computer. All intermediate variations are possible within these two extreme steps. For instance, in the "swinging-door shop" there is a special group mostly comprising engineering technicians, who have a thorough knowledge of the computer. The engineers direct the programming work, but utilize this group for coding, debugging, and operating details. In other variations, one or more programming experts are available, to advise the engineers who do their own programming when these encounter difficulties or otherwise require help in the various stages of their work.

Returning now to the two extreme cases, the closed shop and the open shop, it is clear that both have their advantages and disadvantages. The open shop has all the well-known advantages of decentralization. The engineers are responsible for the entire process; there are no barriers of working knowledge or organization between them and the computer; they have knowledge of the entire process and thus consider the computer as an extension of their knowledge and as an adjunct or helper rather than as a little-known stranger who threatens to take away their job. Individual characteristics of each engineer are reflected in the programs and there is less of a shock in the transition from the traditional design methods to the new computer methods. This approach also avoids the bugaboo, more imagined than real, of concentrating all the knowledge and decision-making in a small group of "experts." Probably this type of organization is best for small and medium-sized computers, in the initial stages, and where there is a great variety of jobs which are not run regularly and often, on the computer.

The closed shop also presents many advantages. As mentioned, programming represents in any computer installation a considerable, if not the most important, investment of time, money, and effort.

This is particularly true for larger machines, and when the data-processing content of the job is high. Therefore management will want the investment kept within reasonable limits, and to yield a high rate of return. Also, a new computer is often loaded up to capacity within a relatively short time, and prospective applications clamor for more time. This means going to another shift or obtaining another machine, with a corresponding increase in rental and operating cost. In short, the circumstances invariably lead toward the most efficient use of the programs and of the available computer time. It is a fact that two identical applications (i.e., those having the same input and output) may correspond to programs of widely different length and complexity and to running times of ratios as high as three to one. Thus the total cost of an application may vary very considerably, depending on the ability and training of the programmers, the organization, the pattern of communications, etc. In many cases this may spell the difference between the success and the failure of the application, technically and economically.

For complex, expensive, and highly repetitive applications, there is therefore considerable merit in having a group of professional programmers, thoroughly trained in the use of the machine being used, and assigned full time to a given class of applications. It takes at least 3 months to train thoroughly a programmer, and even more time to become an expert in the procedural and communication aspects of any application. In line with the present tendency of science and engineering towards more marked specialization, all programming and debugging is entrusted to a group of professional specialists, programmers, coders, and operators. Among these may be found specialists in input and output forms, use of auxiliary equipment, automatic programming, numerical methods, cost estimating procedures, etc. It has been stated repeatedly that 10 to 20 persons are required to "keep busy" a medium sized computer, and 30 to 60 persons a large one. Problems of planning, organizing, integrating, and measuring the activities of such a large group of highly specialized persons make it almost mandatory to have a separate organization with its own authority, responsibility, and accountability. Such an organization is also more attractive in hiring and keeping programmers, which are at present very scarce and relatively expensive, because it provides the feeling of togetherness, the possibility of self-development, and more opportunities for promotion. Also, the contacts and communications between the programming and operations group, vital for the success of the application, may be better formalized, and conducted more efficiently. For all these and similar reasons, a separate programming component appears preferable for a large installation, for complex and difficult applications, and for those with high data-processing content.

In the closed shop there is the danger, real or imagined, of concentrating all the working knowledge and decision making in this group and, in fact, of creating a duplicate of the engineering office, with ensuing rivalries, jealousies, and "empire-building" tendencies. Of course, this is the same problem encountered in every line-staff relationship, and management can very well take care of it. The programming group must be reminded that it is strictly a service organization and that the responsibility of designing the product still remains entirely in the design component. It is also necessary to maintain continuous and effective formal and informal communication between engineers and programmers. In many cases, transfer of personnel between the two groups is an excellent source of cross-fertilization of ideas, new ideas, and better ways of doing things. Generally speaking, it is easier to teach programming to an experienced engineer than to teach a particular branch of engineering, such as transformer design or stress analysis, to an experienced programmer. (Besides, the latter are in short supply, and employing them is costly.) Thus, in most cases, the programming group will consist of several engineers, among them some of the most experienced and able, and there should be no danger of the work of the two groups "going off in different directions." The programmers, however, should not be obtained exclusively from within the engineering office. Some new blood is desirable, in the form of engineers or mathematicians employed from outside the company, to bring in new ideas and techniques, and the experience gained from work with other computer installations. Probably the best ratio is of two programmers transferred from other groups in the plant to every one hired from outside.

Purposely omitted, up to this point, has been any discussion of the reporting organization of the various components, that is, whether they should be part of engineering, finance, general administration, or of a separate *ad hoc* computer component, reporting to the department or plant manager. We feel that this much-discussed and still controversial aspect of the problem is less important than the recognition that there are three different kinds of work. In practice, all of the aforementioned solutions in all their possible combinations have been tried. For instance, in some installations engineering is responsible for programming and running the computer, in addition to its usual duties. In other cases, the financial section is responsible for programming and running the engineering applications and it has several mathematicians assigned to its computer groups. Many other organizational patterns exist, and they apparently operate quite sucessfully.

THE PITTSFIELD CPC AND IBM-705 INSTALLATIONS

To summarize the authors' experience in Pittsfield, at first the CPC was assigned to the advanced development component of the power transformer department and operated more or less as a closed shop, three engineers being responsible for all the programming. The responsibility of operation was shared between the two computer operators and the engineers themselves. As soon as the principal programs were completed and performing satisfactorily, the CPC was transferred to the design component and was operated henceforth mostly on the open-shop basis. When it was decided to acquire a *705* and create a large group of professional programmers, a separate component was set up. All programming was done by this component strictly on the closed-shop basis, using the only two systems then available from IBM, the symbolic and the autocoder. Shortly before the *705* was delivered, the computer component was reorganized into two separate units, one responsible for programming as previously, the other for computer operations. As soon as a program is completely debugged and tested successfully for several practical cases, it is turned over by the programmers to the operations component. From then on, the operations people deal directly with the engineering office and are alone responsible for running the jobs. The programmers are consulted only occasionally, in case of particularly difficult jobs, errors, doubtful results, etc., but essentially they have nothing to do on these programs (except for updating) and are free to start working on other applications.

At about the same time, two other types of programming methods became available. One was the CPC programming system, converted automatically to the *705*, as discussed previously.[7] This is very important because there were more than 50 engineers and technicians in Pittsfield who knew how to program for the CPC, but not for the *705*. Now, by this method, they can make use of the *705* without any further training. Early in 1957, IBM made available a new automatic programming system for the *705*, called "Print I" and especially designed for scientific and engineering applications. While the symbolic *705* coding system requires a 4-week course, practically full time, the Print I system may be taught in a week to technical personnel. It may be learned in an even shorter time by those already familiar with CPC or *650* programming. Compared to ordinary *705* programs, Print programs require more time for assembly and for running, since all operations must be interpreted and all calculations are done with 10-digit floating decimal numbers. As has been seen, for design work, four to five significant digits are usually sufficient, and fixed decimal is entirely adequate, since the order of magnitude and range of the various design quantities is known. Thus, machine running time, which in the *705* is proportional to the number of digits carried and to the number of digit shifts, is saved by using ordinary fixed decimal code and variable word length. Nonetheless, Print I is extremely useful and fast for special design and development problems which are not run very often or which are relatively short. Therefore, Print I courses were given to many engineers and technicians who are not part of the computer component. They can now use the *705* on an open-shop basis for any program written in Print I language. An experienced specialist in automatic programming is available within the computer programming group, to advise and help anyone using the Print I system.

We feel that in this manner, the Pittsfield *705* installation combines the high efficiency and professional ability of the closed-shop organizations, for the more complex, lengthy, and highly repetitive programs, with the accessibility and decentralization and spreading of responsibility of the open-shop organizations for the other programs. So far, this system has been working well, and it has met with the approval of both the engineering and programming groups.

Economics

There is no doubt that the most vital questions and the most frequent ones asked by management concerning a prospective or an existing computer installation are, "How much money will it save?" or "How much money is it saving?" In a free-enterprise society, wherein profits and losses are one of the principal indexes of measurement, this could not be otherwise. On the other hand, many difficulties are encountered in assessing the actual dollars and cents saved by a given installation, even after the first year of operation. More difficult is the question of evaluating the savings of a prospective computer application.

First of all, it should be recognized that not all computers are installed to save money. In certain cases, a computer is run as a laboratory devoted to pure research. The scientists are given the tools with which to work in a certain field in the laboratory without any immediate goal of financial returns. Similarly, a computer may be obtained by management so that its scientists, engineers, and financial personnel may experiment with it with a view to finding later good use for it. As is well known, many of the most important advances have arisen from this kind of approach and from the principle of serendipity, and therefore it should not be dismissed too lightly.

In most practical cases, however, the computer is competing, in dollars and in manpower, with other alternate investments, and therefore the decision to obtain or to keep one must be justified economically. The dollars-and-cents aspect may be very important for certain applications, particularly in the data-processing field (for instance, payroll and tax accounting) but very much less so for other applications (for instance, in the advancement of new technologies vital to the national defense). Therefore, the discussion of economics will not be exclusively of dollar savings, but also savings in time and effort, and of other contributions usually defined as "intangibles" by accountants.

The application of digital computers to engineering problems may therefore be justified, for one or more of the following reasons: 1. It saves money. 2. It saves time. 3. It saves the effort of skilled personnel, of which there is at present a shortage. 4. It improves accuracy and the quality of the product. 5. It enables engineers to solve problems which could not be solved without it.

DIFFICULTIES IN DETERMINING SAVINGS

The normal accounting practice in determining the savings which may be attributed to a specific innovation can take into account only reason 1, dismissing the others as "intangibles." Even in the determination of the actual dollars and cents saved, the two alternate methods, by hand and by computer, must be directly comparable, i.e., starting from the same input data, they must produce the same output data, after carrying out the same computations and logical decisions. This may be the case for a standard payroll application, which starts from the employee's clock cards and produces pay checks, and various accounting reports. It may also be the case for certain relatively simple and repetitive mathematical problems, for instance, the solution of four or five simultaneous linear equations. An engineering assistant with a desk calculator will require so many hours, a computer so many seconds, and thus a direct comparison is possible if the total costs per unit of time are known. In the great majority of cases, however, engineers want to use the computer not just to repeat narrowly and uncreatively what was being done previously by hand, but rather to obtain the best possible result, with regard to accuracy, quality, and speed, or to discover solutions to previously unsolved problems. This, of course, is the right approach and the only one conducive to technological and scientific progress. Even if the two alternatives were exactly the same in procedure and quality, they might not be the same in quantity. For instance, with the computer readily available, engineers will usually solve many more systems of linear equations than previously, in order to try out more alternatives of the same problem. Since, strictly speaking, one can only "save" the money that he was spending previously, it is hard for the accountant to assess the "savings" corresponding to work which was not done previously.

Even assuming that the computer does exactly the same work, in quality and quantity as previously done by other means, it may be difficult to evaluate the actual dollars saved. This will be made clear by the following hypothetical example. In three identical engineering sections, consisting each of 100 employees, 70 were employed for production design work and 30 for development work. After the introduction of a computer to do design work, only 30 employees are now necessary to complete the same amount of production. Furthermore,

1. In the first section, the same amount of production is now being done with 30 employees. The other 40 were released for other work outside the section.

2. In the second section, 40 production

design people were shifted to more highly paid jobs in development within the section.

3. In the third section, no changes were made in personnel, but the number of designs produced by the production group of 70 people was more than doubled. These additional designs are used to take care of the increase of business, to reduce the amount of material and labor by considering the best alternatives, to improve service on customer applications, etc.

It is clear that only in case 1 have actual savings been made in dollars and cents for that section. In case 3 the savings are no less real, but are for the entire department in reduced manufacturing cost and in increased business. In case 2 the budget of the section has actually gone up in order to obtain increased profits in the future by stepping up the development effort. The important point is that in all three cases the "gross savings" attributable to the computer are exactly the same, namely, 40 production people. In dollars this would correspond to the total salaries plus overhead. The contribution of the computer is totally unassociated with the decision of how and when to use the 40 people it has displaced. This decision is strictly the responsibility of the management of the section involved.

In addition to the savings just discussed which may be attributed legitimately to the computer, there are other savings, no less important, which are achieved concurrently to the introduction of the computer. Both in data processing and in engineering, these savings arise from improved practices and procedures, standardization, elimination of useless forms and reports, etc. It has been stated several times, half seriously and half facetiously, that every company should order a computer, prepare for it, and then cancel the order. In this manner, considerable savings would be realized, through improvement and streamlining of existing obsolete procedures. This statement applies also to engineering, particularly to design, and up to half the savings obtained with the use of computers may be attributed to improved methods and standardization; the remainder to the computer itself. The point, however, is that none of the savings were actually realized without the computer, which acted as the catalyzer of the entire process. After all, management is interested in the total savings obtained, and it is a moot question as to how much should be attributed to procedure improvement by itself, how much to the computer by itself, and how much to the interaction of these two factors.

THE "GROSS CONTRIBUTION"

The foregoing discussion has shown that the determination of the potential or actual savings attributable to a computer is far from simple, even if one is restrained from placing a dollar tag on intangibles like time, service, quality, accuracy, more complete and quicker information, etc. In conclusion, the discussion will be of the "gross contribution" or "net contribution" attributable to the computer, rather than of gross savings or net savings. The latter is strictly an accounting problem, and undoubtedly each company will solve it according to its established practices. Therefore the authors believe that the gross contribution attributable to a given computer should be figured out on the basis of the cost of doing with the tools previously available the same jobs in quantity and quality as are now done on the computer. In this manner the gross contribution may be evaluated with respect to hand methods, conventional punched-card equipment, and other types of computers (usually smaller ones). The net contribution is obtained by subtracting the total computer cost from the gross contribution. These costs will be discussed in the following section.

COMPUTER COSTS

The over-all costs encountered in the application of digital computers to engineering problems may be divided into two categories: 1. investment costs, consisting of the sum of programming costs (including debugging), physical installation costs, and starting-up costs (such as running in parallel for a certain period, conversion of basic data to punched cards and magnetic tape) etc.; and 2. running expense, which includes computer rental, salaries of operating personnel, supplies, and overhead. These two categories correspond to the two different kinds of work discussed in the section entitled "Organization."

Scientific programming cost may vary between $1.00 to several dollars per computer instructions, as quoted in the literature. The higher figures are for complex data-processing applications, and for the larger computers. Of the total amount, approximately one third represents debugging costs. Since an engineering program may have between several hundred to several tens of thousands steps, the programming costs may be any amount from several hundred dollars to $100,000 or more. Even higher amounts are possible for data-processing applications, and figures from $4.00 to $10.00 per computer instruction have been quoted in the literature. The cost of the physical computer installation includes the costs of preparing the computer room, the auxiliary punched-card equipment room, the programming office, the power supply, the air conditioning, etc. They may vary from $10,000 for a small installation to several hundred thousands for a large one. The prorating of these costs to the various jobs done on the computer may be done in various ways; it is essentially an accounting problem. One way is to prorate the cost according to total running time of each job per year. The start-up costs are usually much smaller for engineering than for data-processing applications. They probably are worth considering only for engineering data-processing applications such as design synthesis of complex apparatus.

Running expense, for one shift, will be any amount from less than $100,000 per year for a medium-sized machine without tapes to $600,000 or more for a large machine. As noted, the running cost per operation is less, the larger the machine, since the speed increases much faster than the cost.

As has been mentioned, total costs for a given application may vary widely depending upon the ability of the programmers and, in a lesser degree, upon the computer selected and the ability of the operators. It is also possible to trade programming costs for running expense. For instance, a "tight" program with many loops is more difficult to program and to debug, but it takes less time to run than a "loose" program. This consideration is at the basis of many automatic interpretative programming methods, wherein ease and speed of programming is paid in part by longer running times. Similarly, it is possible to use for the same group of applications either one general program which will process all possible combinations of the input; or several special programs, each for a particular application. The smaller the computer, in general, the less general the program. Since loading time may be quite expensive for a large computer, a general program is usually cheaper to run than several separate programs. A more general program, on the other hand, is more difficult and laborious to write and debug, since its various portions are interrelated by loops and its complexity increases faster than the number of program instructions. For preliminary design of transformers on the CPC, different program decks were used for different types of components,

Vol.
Pt. 1
1958

e.g., windings. These decks were selected and collated manually by the operator. In the *705* there is only one program for the preliminary design of all power transformers, regardless of rating, number of windings, etc.

In conclusion, over-all computer costs are very much dependent upon the ability of the programmers and operators, who must adapt their techniques to the specific characteristics of the application and of the computer being used. Having thus discussed methods for evaluation of the gross contribution of the computer and of the over-all costs, these methods will now be used to determine the net contribution of a specific application in power transformer design. Relative contributions and costs will be used rather than actual dollars, because the actual costs vary so much between different intallations and, furthermore, are not usually available. Therefore it is felt that relative values will be more significant and more broadly applicable for comparison with the economics of other engineering applications.

TRANSFORMER REACTANCE CALCULATION

A typical example of an engineering application of small-scale and large-scale digital computers is the calculation of reactance between any pair of concentric transformer windings. Several of these calculations must be performed for each transformer design, and the specified impedances must be met in test within relatively narrow limits. In brief, conventional methods of calculation by hand have always assumed that the windings are flat, without curvature. This, of course, is not the case in practice, and this assumption loses its validity when the ratio of the gap between windings to the average radius is large, as, for instance, in multiwinding transformers, or when the windings are axially nonuniform. The errors introduced from this cause may occasionally result in rejection of a unit after it is built, when the impedance test shows that the guarantees have not been met. In any case, this limitation requires higher design safety factors, and closer manufacturing tolerances which, in turn, mean higher cost. While this problem had been recognized for many years, it always appeared impractical, if not impossible to introduce curvature into the reactance calculations by hand, because of the Fourier series and the Bessel asymptotic series involved, all with a large number of terms.

After the CPC was installed in Pittsfield, a program was developed for calculating reactance by the circular field method between any two transformer windings.[4] An extensive comparison of calculated and measured values showed that the accuracy of this method was considerably higher than the accuracy of the hand method. Since the CPC was loaded to capacity, and because 80 minutes were required for one reactance calculation (compared to a minimum of 60 engineering hours by hand) only the most important designs were checked by this system. When the *705* was installed, a new fixed-decimal program was prepared for this computation, requiring only 57 seconds to run. Table II shows a comparison of times and relative costs for the three methods: by hand (which was never used in practice), by CPC, and by *705*. It is evident that the time and cost of this accurate method, using the *705*, is insignificant. In fact, less time and lower cost were involved than in doing the same calculation by the approximate method, by hand. Therefore, reactances of all power transformers are now computed by *705*, thus ensuring the highest accuracy in all cases, and eliminating totally the eventuality of rejection in tests. It is interesting to note from Table II that, while the CPC achieved a very important reduction in cost with respect to hand methods (89%), the introduction of the larger computer achieved considerable additional savings (from 89% to 98.7%). More important, it was only the extremely short-running time on the large computer that made the adoption of this method possible for all power transformers, rather than for only a selected few.

Table II. Comparison of Times and Costs for a Reactance Calculation

	By Hand	By CPC	By 705
Time	60 hours	80 minutes	57 seconds
Relative time	1	1/45	1/3,800
Relative cost per hour	1	5	50
Relative cost per calculation	100%	11%	1.3%

The *705* program has approximately 2,000 computer instructions and it required about 3 man-months to program and 4 machine-hours to assemble, debug, and check out completely. It may be estimated that the ratio of the investment for this program to the running costs for one computation on the *705* is approximately 1,200 to one. From the figures given in Table II, it may be concluded that, with respect to the hand method, the investment will be paid off after 16 computations, and after that the net contribution, of the computer will amount to 98.7% of the cost of one computation by hand. With respect to the CPC, the corresponding figures are 160 computations and 88% of the cost of one computation by CPC. Since several reactance computations are being made each day on the *705*, the period required for paying off the investment, with respect to the CPC, is of the order of 2 months, less time than was needed to write the program. It may be concluded that, even considering the total costs, the *705* is considerably cheaper than the CPC for this application.
